Repair and grafting of peripheral nerve

Kirsty Usher Boyd, Renata V. Weber, Andrew Yee, and Susan E. Mackinnon

Access video lecture content for this chapter online at expertconsult.com 

SYNOPSIS

- Primary neurorrhaphy remains the gold standard in nerve repair; all other methods of repair are judged in comparison to primary neurorrhaphy.
- Following any mechanism of repair, nerve regrowth occurs at a maximum of 1 mm/day, making distance from end-target muscle the most important prognosticator for recovery.
- Excessive tension will inhibit nerve regeneration, however a small amount of tension to achieve primary coaptation is acceptable.
- In the event of a nerve gap, several options for repair exist including:
 - Mobilization and primary coaptation
 - Interpositional nerve autografting
 - Interpositional nerve allograft (acellular or fresh cadaveric)
 - Interpositional nerve conduit
 - Distal nerve transfer.
- Prognosis following nerve injury is impacted by several factors:
 - Patient age and comorbidities
 - Location of injury (proximal versus distal peripheral nerve)
 - Mechanism of injury (crush versus avulsion versus transection)
 - Timing of repair
 - Method of repair (tension, alignment, scarring).

Introduction

Nerve injuries present a unique problem in patient management due to the prolonged periods of recovery and the necessity of having viable axons reach the end-motor target prior to irreversible atrophy and fibrosis. These patients suffer significant negative impacts including chronic pain, depression, and considerable effect on daily life.¹ In the setting of prognosis, *time is muscle*, with permanent muscle damage occurring as early as one year after denervation. While primary nerve repair and grafting have not changed significantly in the last several decades, there have been several paradigm shifts as understanding of the internal neural topography has improved

and new techniques and products have become available. The gold standard in nerve repair remains primary neurorrhaphy, however in the situation of a nerve gap, other alternatives are necessary to avoid excessive tension, which causes permanent scarring at the repair site. Autologous nerve grafting has been the procedure of choice for addressing a nerve gap, however donor sites are limited and leave deficits. While nerve autografts are considered the “gold standard” for a nerve gap reconstruction, it should actually be considered a “bronze standard” as results are never normal. Other alternatives include acellular nerve allografts, conduits, and nerve transfers. This chapter reviews the various methods of addressing a nerve injury, with emphasis on surgical decision-making, timing, and prognosis.

Basic science/disease process

Types of nerve injury

As seen in [Table 19.1](#), nerve injuries can be classified based on their degree of damage and the components of the nerve that have been affected. While this method of classification is useful for prognosis and surgical decision-making, the mechanism of injury also provides a useful method of classification that allows for an algorithmic approach to treatment. Nerve injuries can therefore be classified as either open or closed, and then subdivided by mechanism of injury as penetrating injuries, avulsion or crush injuries, or stretch and avulsion injuries.

Penetrating injuries

Penetrating trauma can be a result of sharp or blunt penetration and will often have concomitant injuries to adjacent structures such as blood vessel, tendon, and muscle. A sharp

Historical perspective

The history of nerve injury

A peripheral nerve can be classified in several ways. Historically, the first classification system by Sir Herbert Seddon (1943) was based on gross and histologic anatomical changes rather than mechanism of injury.² He described three types of nerve injuries:

1. Neurapraxia: involves a local conduction block at a discrete area along the course of a nerve.
2. Axonotmesis: implies direct axonal damage.
3. Neurotmesis: implies transection of the peripheral nerve.

In neurapraxic injuries, Wallerian degeneration does not occur and the prognosis is excellent with anticipated recovery of full strength and function. In both axonotmetic and neurotmetic injuries, Wallerian degeneration occurs distal to the site of injury. Recovery is possible within an axonotmetic injury, but Seddon described a degree of scarring and less complete recovery within this type of nerve injury. In neurotmesis, there will be no recovery. Sunderland expanded upon the earlier Seddon classification and emphasized five degrees of nerve injury.³ Mackinnon later went on to include a sixth degree (see [Table 19.1](#)).^{4,5} Understanding the degree of injury is helpful to predict recovery. It is anticipated that a first-degree neurapraxic injury will make a full and speedy recovery. Second-degree axonotmetic injuries will make a full recovery at the classic rate of 1–1.5 mm/day.⁶ Fourth-degree axonotmetic injuries, also known as a neuroma-in-continuity, and fifth-degree neurotmetic injuries do not recover. Third-degree axonotmetic and sixth-degree (multi-level) injuries recover partially for different reasons. The difficulty with surgical correction of a sixth-degree injury is limiting the repair to

fascicles affected by fourth- and fifth-degree damage, and not damaging adjacent fascicles with potential for spontaneous recovery.

The history of nerve grafts

Current practices that account for the success of nerve grafts include the use of small, thin grafts that are cabled when necessary. Historically, when nerve trunks were used as grafts, poor results ensued.⁷ Small, thin grafts revascularize more easily than larger nerves and this contributes to the success of functional outcomes. The maximum length that may be bridged by a nerve graft is controversial. In general, results fall off and are less predictable at lengths greater than 6 cm. However, 20 cm and longer nerve grafts have been used with varying degrees of success.^{8,9} Taylor and Ham introduced free vascularized nerve grafts in 1976 in order to treat these longer gaps.¹⁰ For smaller defects, a vascularized graft and conventional graft do not appear to differ in clinical outcome, however Doi *et al.* recommend using free vascularized nerve grafts when the gap distance is greater than 6 cm with associated soft-tissue loss over the repaired area.¹¹ Currently, the indication for a free vascularized nerve graft is for reconstruction larger-diameter nerve grafts, such as the ulnar nerve, in brachial plexus avulsion injury.^{11–13}

The history of conduits

Biological conduits, including bone, artery, collagen, vein, muscle, and small-intestine submucosa have been used.^{14–17} Biodegradable synthetic conduits such as polyglycolic acid are currently used, while nondegradable nerve guides made from silicone have fallen out of favor.¹⁸ Their major disadvantage is leaving foreign material that potentially causes a chronic reaction with excessive scarring.

Table 19.1 Classification of nerve injury

Seddon	Sunderland	Injury	Recovery
Neurapraxia	Degree I	Conduction block resolves spontaneously	Fast/excellent
Axonotmesis	Degree II	Axonal rupture without interruption of the basal lamina tubes	Slow/excellent
	Degree III	Rupture of both axons and basal lamina tubes, some scar	Slow/incomplete
	Degree IV	Complete scar block	None
Neurotmesis	Degree V	Complete transection	None
	Degree VI (Mackinnon)	Combination of degree I–IV ± normal fascicles	Mixed

laceration, such as from a knife or a piece of glass, will almost always necessitate exploration if a nerve deficit is present on initial clinical examination. The likelihood that the nerve is partially or completely transected is high. These injuries should be explored within 72 hours if distal stimulation using an intraoperative nerve stimulator is needed. In addition, the further from the time of injury, the more difficult mobilization of the proximal and distal ends to coapt primarily becomes. In the event of a penetrating trauma associated with a vascular injury, immediate exploration is warranted. Unfortunately, in significant proximal injuries necessitating arterial reconstruction with or without underlying fractures, a nerve injury can be overlooked due to the more urgent vascular and orthopedic injuries. In these situations, when a nerve deficit is noticed postoperatively, it is unclear if the nerve injury is from the inciting event, iatrogenic during the repair of the other injuries, or secondary to edema or hematoma. While a computed tomography scan or magnetic resonance imaging may be helpful to evaluate for the latter, internal scarring of the nerve may not always be clearly determined.

Blunt penetrating and blast injuries, such as gunshot wounds or injuries due to an incendiary device, are often managed conservatively similar to closed crush and traction injuries. There is potential for spontaneous recovery. Local tissue edema often causes a neurapraxia, which should resolve within 12 weeks. If recovery is not evident on serial clinical examination and electrodiagnostic studies by four months, the algorithm for a crush injury should be followed (Fig. 19.1).

Crush injuries

Crush injuries are common peripheral nerve injuries to the upper extremity. External crush may be complicated by increased internal pressure from hematomas, fractures, and local tissue edema. When minor, this may cause a temporary neurapraxia, but with greater compression, the likelihood of a permanent injury increases. The most severe consequence of a soft tissue crush injury is the progression to compartment syndrome, which is a surgical emergency. Often an early sign of impending compartment syndrome is a decrease in vibration sensibility.¹⁹

While nerves are fairly resistant to injury given their elasticity, a mixed nerve injury can often occur. A more extensive crush injury can cause local tissue damage that contributes more to the loss of function than the original nerve injury. Muscle tissue is the most susceptible to external forces. Even if the injury is not significant enough to cause a compartment syndrome, the local destruction of muscle may lead to muscle necrosis. Tendon and skin are more resistant and can

withstand higher compressive forces before irreversible damage to the cells results.

The nerve portion of a crush injury is usually treated conservatively. Exploration is warranted if nerve recovery does not follow the anticipated pattern of recovery based on distance from injury to end-target muscle. Along with avulsion injuries, the treatment algorithm for a crush injury involves serial clinical examination and electrodiagnostic studies as dictated by the anticipated recovery (Fig. 19.2).

Stretch and avulsion injuries

When the strain on the nerve exceeds a certain limit, the internal structure of the nerve becomes injured without any appreciable external evidence of injury. Nerves that are stretched to the point of avulsing from their proximal origin suggest a high-velocity, or high-impact, injury that is often associated with limb or life-threatening injuries that take precedence over the repair of the nerve. The nerves tend to be avulsed around areas of tethering, such as bony foramina or the spinal cord. If the proximal nerve can be accessed, grafting of the nerve may be possible. For areas such as the cranial nerves or the spinal roots, where the portion proximal to the avulsion is not accessible, reconstruction is typically done by either nerve or tendon transfers.²⁰ The algorithm for treatment of these injuries involves focusing first on the nerve injury, with repair or reconstruction dictated by degree of injury, followed by procedures to augment recovery such as tendon transfers and joint arthrodesis (see Fig. 19.2).²¹

In situations where no distal nerve is accessible, such as avulsions from the neuromuscular junction, implantation of the proximal nerve directly into the muscle to neurotize the muscle is an alternative. Some studies show as good as MRC 4/5 motor recovery 1–2 years after direct nerve to muscle neurotization, however experimental studies do not support these findings; rather, recovery is much less than a nerve coaptation would produce.^{22,23}

Hints and tips

Sharp penetrating injuries with an acute nerve deficit should be explored early (within 72 hours) if stimulation of the distal end is needed to perform a primary neurorrhaphy. Crush and traction injuries should be treated conservatively with serial examination and electrodiagnostic studies at regular intervals based on expected recovery.

Fig. 19.1 Algorithm for penetrating injury and lacerations.

Diagnosis/patient presentation

A thorough history and physical examination remain the mainstay of diagnosis for a peripheral nerve deficit. A component of experience in recognizing common patterns of nerve injury can facilitate this.

Sensation can be tested using Semmes–Weinstein filaments, two-point static and moving discrimination, or the “ten test”.

The quick and easy “ten test” uses the patient’s own subjective perception to moving light touch to elicit differences in sensation, using the contralateral digit as a reference point.²⁴ This technique is particularly useful in young children, who may have difficulty cooperating with two-point discrimination, or with rapid assessment of a patient being rushed to the operating room for an associated vascular injury.

Motor deficits are recognized by focused examination of all muscle groups in the upper extremity, with patterns

Fig. 19.2 Algorithm for closed traction injury, stretch injury, or avulsion injury.

of weakness or inactivity being used to diagnose the involved peripheral nerve.

In patients with an acute deficit, determination of whether the nerve will recover spontaneously, or whether surgical intervention is required, can often be difficult. The mechanism of injury can assist in preoperative evaluation. Any sharp, penetrating injury should be explored within 72 hours. Similarly, any injury where there is a high index of suspicion for nerve transection should be explored and repaired. The

advantage to early repair, and specifically repair within two weeks, is that the proximal and distal nerve ends have not retracted and primary neurorrhaphy is often possible. Closed traction injuries, partial avulsion injuries, and crush injuries with an associated nerve palsy are more difficult to evaluate. Waiting 3 to 4 months with serial clinical and electrodiagnostic examination is advocated.

The electrodiagnostic signs of an axonotmetic injury, particularly fibrillations and positive sharp waves, may not

be present for at least three weeks from the time of injury, once Wallerian degeneration has occurred. For this reason, electrodiagnostic studies at the time of injury are not recommended except to document any pre-injury pathology. Regular electrodiagnostic testing, and specifically electromyography, is advocated due to the fact that EMG changes precede clinical recovery by months. In closed injuries, if there is no evidence of recovery in the form of motor unit potentials (MUPs) by 3 to 4 months, surgical exploration and reconstruction are warranted. The presence of MUPs by three months suggests at worst a third-grade injury, which should recover spontaneously at the rate of 1 mm/day.

The role of imaging in the clinical investigation of nerve injuries is more controversial. New ultrasound machines have the resolution to detect digital nerve neuromas, however these studies are still largely investigational and are highly operator-dependent. There is some early evidence that ultrasound is more sensitive (93%) than MRI (67%) with similar specificity (86%), however this is more typically in the setting of nerve pathology.²⁵

Hints and tips

Clinical evaluation at the earliest opportunity, followed by serial clinical examination and electrodiagnostic studies, are critical in the diagnosis and assessment of a nerve deficit. Recognizing patterns of recovery or the lack thereof can facilitate decision-making regarding timing an operative intervention.

Patient selection

Nerve injuries often occur in the setting of concomitant injuries and sometimes multi-organ system trauma. Unlike in the elective surgical patient, there is little ability to select an ideal patient.

The importance of recognizing the impact of concomitant injuries cannot be overstated. Patients should be stabilized, with repair of life-threatening injuries (such as vascular laceration) taking priority. Bony fixation and fracture immobilization generally precede nerve repair, as the possibility of iatrogenic injury to the microscopic nerve repair is high.

Wherever possible, nerve repair should be performed during daytime hours, with proper operating equipment and well-versed operating staff. An operating microscope and loupe magnification should be used to explore and identify cut nerve ends. Experienced surgeons will facilitate surgical decision-making based on method and level of injury.

Treatment/surgical repair

Prompt, tension-free, primary neurorrhaphy is universally held as the ideal repair, and multiple animal studies support the idea that single nerve repair results in a better outcome over a nerve graft.²⁶ With each repair site, a percentage of fibers are lost, therefore fewer neurorrhaphies ensures a greater percentage of proximal nerve axons reaching the target endplates. Some investigators believe that as many as 50% of regenerating sensory or motor axons may never reach

the correct end-target.²⁷ Recent studies also show that Schwann cell senescence occurs as graft length increases.

In the event that a primary repair is not possible, mobilization of the proximal and/or distal nerve ends may overcome a small, less than 5 mm, gap because of the elastic property of the nerve.²⁸ If, however, a repair is performed in the face of tension and contamination, unfavorable scarring will occur. In this situation, two neurorrhaphy sites are preferable to a single neurorrhaphy under unfavorable conditions.^{29,30} If primary repair by mobilization cannot be achieved, there are several techniques to address the resultant nerve gap (Table 19.2).^{31,32}

Conduits

The use of conduits to bridge major nerve gaps has been described, but has largely fallen out of favor. For non-critical, small diameter, sensory deficits less than 3 cm, conduits may serve as a potential option. Biological and synthetic conduits are available. Using this method, protective sensation, and in some cases good sensation, have been restored.³³ When using a conduit, placing a small portion of the proximal nerve into the conduit to serve as a source of Schwann cells is recommended.³⁴ More often, the conduits are now used as nerve wraps for protection of a primary neurorrhaphy, however this can be cost prohibitive. Seprafilm[®] adhesion barrier (Genzyme, Cambridge, MA) has been used by the authors placing a small piece above and/or below the repair.

Nerve grafting

Autologous nerve grafting

The most common technique for addressing a nerve graft is interpositional nerve grafting. Autologous nerve grafts are the gold standard or better termed bronze standard. The nerve graft serves as a guide for the axon as it regrows towards the distal stump (Fig. 19.3). Although the sural nerve is most commonly used as a donor nerve, our algorithm for selecting autograft donors has evolved away from this donor (Table 19.3).^{32,35–37} Wherever possible, donor nerves within the affected extremity and available through the same surgical incision are selected.³⁸ Experimental studies comparing motor, mixed, and sensory grafts support the idea that motor and mixed nerve grafts achieve better regeneration across the repair.^{39,40} Donor motor nerve grafts, however, are in more limited supply, and in clinical practice, the branch from the obturator to the gracilis and the distal anterior interosseous nerve are the two motor grafts that cause the least morbidity. The obvious downsides of autologous grafting are the limited number of donor nerves available and the resulting donor site morbidity.

Acellular nerve graft

Acellular human processed nerve allografts (ANA) have been introduced as a method for spanning the nerve gap. Initial clinical trials show that recovery for small sensory gaps is better than that for conduits and more comparable to autografts.⁴¹ This human tissue retains its three-dimensional structure, including epineurium, fascicles, endoneurial tubes and laminin, and it is believed that the scaffold allows for repopulation of the host cells, similar to autologous tissue (Fig. 19.4).

Table 19.2 Options for management of the nerve gap

	Advantages	Disadvantages
Nerve autograft	Gold standard for reconstruction Schwann cells in extracellular matrix	Second operative site Results in donor sensory loss Potential for neuroma formation/pain Sensory nerve autografts do not support motor regeneration as well as motor or mixed sensorimotor nerves Limited available length
Allograft	Can potentially allow functional recovery equivalent to autograft No donor site morbidity	Requires patient systemic immunosuppression (~18 months) Patients vulnerable to opportunistic infections
Conduits	Circumvents adverse effects of autografts and allografts Guides regenerating nerve to intended target	Length limitation (<3 cm) Only for small-diameter sensory nerves No Schwann cells No matrix Expensive
Acellularized graft	Retains scaffolding matrix of nerve tissue Nonimmunogenic and inert Biological substrate for nerve regeneration without need for immunosuppression	Length limitation (<5 cm) No Schwann cells Only for small-diameter nerves Very expensive
End-to-side	No length limitation	Poor sensory results Motor requires donor neurectomy
Reverse end-to-side	Augment partial motor/sensory nerve injury	Requires knowledge of topography Requires knowledge of expendable donors May need nerve autograft or acellular graft
Nerve transfer	Earlier motor/sensory target recovery	Requires expendable donor Requires motor (sensory) re-education Requires knowledge of nerve topography

These grafts shorten operative time and eliminate donor deficit, however they are expensive. The ANA handles similarly to an autologous graft, and may be secured via suture or sealant. ANAs have been shown to be superior to an empty conduit, however they are inferior to autograft.⁴²

In the authors' practices, ANAs have largely replaced the use of conduits, and are appropriate for small-diameter, noncritical short (less than or equal to 3 cm) nerve gaps. These grafts are never used for large-diameter gaps, motor defects, or used to bridge a long gap. ANAs are dependent on proliferating Schwann cells from the host tissue. Axonal regeneration and functional recovery have been demonstrated to decrease with graft length and are inferior to autograft at all lengths.⁴³ The mechanism appears to be in part Schwann cell senescence induced by ischemia and cellular proliferation. Transplanting Schwann cells into ANA has been shown to improve functional regeneration closer to isograft levels in a laboratory setting.⁴⁴

ANAs undergo differing processing methods and there is some evidence that this may impact functional outcome. Three models of acellular nerve allografts were examined in a rat model, and the differential processing for removal of cellular constituents in preparing the ANAs were found to affect recovery *in vivo*.⁴⁵

Nerve transfers

Over the past decade, there has been a paradigm shift towards the use of nerve transfers in the restoration of function

following nerve injury. In 2011, Garg *et al.* performed a systematic analysis that demonstrated that when international data were pooled, nerve transfers were strongly superior to nerve grafting in upper brachial plexus injuries.⁴⁶

The principles of nerve transfer are to use expendable, pure donor fascicles. Nerves with redundant fascicles or branches make excellent donor nerves. Because the nerve transfer does not rely on the amplitude and excursion of the tendon muscle unit, unlike tendon transfers, and is not limited to one function, nor a straight line of pull, the muscle-tendon balance can be maintained. The major advantages of a nerve transfer over that of a tendon transfer are that: (1) nerve transfers can restore sensibility in addition to motor function; (2) a nerve that innervates multiple muscle groups can be restored with a single nerve transfer; and (3) the insertion and attachments of the muscle are not disrupted, thus the original muscle function and tension are maintained. Synergistic nerve transfers are preferred because of the ease of rehabilitation.

Nerve transfers are advantageous compared to long nerve grafts because they have the ability to convert a proximal, high-level nerve injury into a low-level nerve. This is particularly important in high median and ulnar nerve injuries to achieve restoration of hand function. Nerve transfers facilitate operating outside the zone of injury and have the advantage of a single neurorrhaphy.

Nerve transfers are possible because of the redundancy existing in proximal, mixed nerve fibers. Knowledge of the internal topography facilitates the separation of fascicular groups even in the proximal extremity; fascicular groups run

Fig. 19.3 Nerve autograft. A patient presenting with (A) a neuroma-in-continuity of the median nerve at the level of the carpal tunnel. The neuroma (B) was resected and treated with (C) cable grafting using medial antebrachial cutaneous nerve (MABC) as a donor.

adjacent to each other in a consistent pattern within the larger nerve itself.⁴⁷ Intraoperative electrical stimulation with a hand-held device (Vari-Stim®, Bio-Medicine) can be used to identify and confirm specific function.

Bioengineering

The need for a bridge or scaffold that successfully allows regenerating axons to reach the end-target muscle in the

setting of a nerve gap has been long recognized. While multiple bioengineering projects have started investigating a solution to this challenge, none so far has succeeded.^{48–51}

Johnson *et al.* have recently described the characteristics of an ideal tissue-engineered construct, including the goals of creation.⁵²

Method of repair

Timing of repair

Patients with an index of suspicion for potential nerve transection are taken to the operating room within 72 hours for exploration and primary repair. Nerves repaired within 48 hours are considered repaired primarily. Delayed repair occurs between 2 and 7 days, and requires freshening of the distal and proximal ends prior to coaptation. Nerves repaired after the first week are considered to be secondarily repaired. While these times are arbitrary, it is clear that the longer the

Fig. 19.4 The nerve allograft (A) can be chosen to match the width of the injured nerve. Here are two different size grafts that were sutured in place with 9-0 nylon sutures after resection of two digital neuromas (B).

Table 19.3 Characteristics of nerve autograft donors based on published literature

Donor nerve	Harvestable length	Fascicle count	Cross-sectional area	Disadvantage	Advantage
MABC	Up to 28 cm	7–10	2–3.15 mm ²	• Medial arm scar	• Long length and larger caliber nerve suitable for larger nerve gaps and/or multiple cables required • Can minimize donor morbidity with end-to-side repair of distal end MABC to median nerve
LABC	5–8 cm	4–9 5–18 6–15 5–7	1.3–1.8 mm ²	• Visible forearm scar	• Good for short gaps • Good size match with digital nerve • Usually injured with SBR and therefore good nerve graft for SBR injuries • Dermatome overlap with SBR reduces donor morbidity
TWM ^a	24.5 cm	2–13	4.43 mm ²	• Sensory loss in hand (non-critical)	• Easy access through volar distal forearm incisions
PCM ^a	Mean length 5.24 cm			• Sensory loss in palm	• Easy access through volar forearm incisions
DCU ^a	Up to 26 cm • Dorsal-ulnar hand divisions, 5–6 cm		2.4 mm ² at origin	• Sensory loss to dorsal-ulnar hand and digits	• Useful if ulnar nerve already injured and working in same operative site
AIN ^a		3–5	0.6–0.7 mm ²	• Deep dissection into pronator quadratus • Short segment available	• No sensory loss • Good size match with digital nerves
PIN ^b	2.5 cm	2	0.5–0.8 mm ²	• Visible dorsal incision • Small diameter graft	• No cutaneous sensory loss
SBR ^a				• Potential for hypersensitivity in donor territory	• Consider if radial nerve already injured
Sural	30–50 cm	9–14 MSC 1–3 LSC 5–7	2.5–4 mm MSC 1.5 LSC 1.5	• Positioning difficult • Requires second extremity	• Long length
Obturator	9.9–13.6 cm 11.5 cm average	2–4		• Loss of gracilis as possible future free functional flap	• No sensory loss • Expendable motor nerve graft

AIN, anterior interosseous nerve; DCU, dorsal cutaneous branch of ulnar nerve; LABC, lateral antebrachial cutaneous nerve; LSC, lateral sural cutaneous; MABC, medial antebrachial cutaneous nerve; MSC, medial sural cutaneous; PCM, palmar cutaneous branch of median nerve; PIN, posterior interosseous nerve; SBR, radial sensory nerve; TWM, third webspace branch of median nerve

^aUsed as non-critical portion of injured nerve

^bTerminal branch

time from injury, the less likely that a primary neurorrhaphy can be achieved, even with significant mobilization of the proximal and distal nerve ends.

Tension

Excessive tension across a nerve repair is known to increase the scarring at the coaptation site, thereby impairing axonal regeneration. In an uninjured nerve, a 15% strain of the nerve causes a reduction in microvascular flow and a delay of peak velocity.⁵³ Clinically, the tension across a repair is never measured, however inseting with any tension is

meticulously avoided. The authors also denounce postural manipulation of the extremity to facilitate tension-free repair, as this increases the likelihood of dehiscence and stiffness due to immobilization.²⁹

Type of repair

The suture diameter is clinically selected based on the size of the nerve. Giddins *et al.* demonstrated in a cadaveric study that 9-0 nylon was the optimal suture to acutely repair the median nerve.⁵⁴ At a lower tension, 10-0 nylon sutures snapped and 8-0 nylon sutures pulled out of the nerve tissue.

Several surgeons advocate for the use of fibrin glue, in place of sutures, especially when there is no tension. Laser energy for epineurial coaptation has been investigated, but causes heat damage and decreased tensile strength. The gold standard remains microsuture under the operating microscope. The authors routinely use a combination of suture and fibrin glue.

Epineurial repair is the preferred method of coaptation once the severed ends are surgically freshened. External markers such as a vessel on the surface and matching the fascicular patterns are used to align the fascicles without overlapping (Fig. 19.5). For major peripheral nerves, an argument for perineurial repair can be made to improve alignment of the larger fascicular groups individually, however clinical studies support both techniques as equally effective as long as the fascicles were not overlapped (Fig. 19.6).⁵⁵ The disadvantage of perineurial repair is that the extensive dissection and the permanent intraneural stitches can lead to increased fibrosis.⁵⁶ In practice, it is often difficult to align the fascicles accurately, as trauma, edema, and scarring can distort the normal topography.

Fig. 19.6 Good alignment of the fascicles (A) is crucial to optimal outcome, whereas bunching and overlap (B) produces an inferior result.

(A)

(B)

(C)

Fig. 19.5 Schematic depicting an epineurial (B) versus perineurial (C) repair after transection of the nerve (A). The native artery and the fascicular pattern are used to align the neurorrhaphy properly. The least number of epineurial sutures using 9-0 nylon is used.

Hints and tips

Using topical landmarks such as longitudinal vessels or fascicular groups for orientation, and the least number of sutures possible to achieve tension-free epineurial repair through gentle, full range of motion, is the optimum method of neurorrhaphy.

Orientation of repair

The majority of nerve repairs are performed in the classic end-to-end fashion. This is irrespective of primary neurorrhaphy or nerve grafting. The role of end-to-side repair continues to be debated. Certainly, end-to-end repair continues to be recommended for all motor, mixed nerves, and sensory nerves in critical distributions. End-to-side repairs for noncritical sensory deficits are acceptable given spontaneous sprouting of sensory nerves. Motor nerves, however, do not spontaneously collaterally sprout; instead, regenerative sprouting occurs following axonal injury proximal to the repair.⁵⁷

The supercharge end-to-side (SETS) technique is used to facilitate early motor axons reaching the target endplates while awaiting proximal regrowth from a high-level injury. This is particularly useful in proximal Sunderland second-degree and third-degree injuries, where long regeneration distance yields prolonged time to muscle reinnervation and suboptimal functional recovery.⁵⁸ The validity of this method of transfer has been confirmed in an animal model.⁵⁹ The classic example would be to perform an anterior interosseous SETS procedure to the ulnar motor branch in the setting of a high ulnar nerve injury, where some recovery is anticipated.

Intraoperative nerve stimulation

A hand-held disposable nerve stimulator may be used to facilitate intraoperative decision-making. While uncomplicated,

clean transections may be equally able to be aligned using topical surface landmarks, in closed traction injuries, especially of the brachial plexus or injuries to larger mixed peripheral nerves, formal intraoperative stimulation may help to identify distal segments. This is also useful if the nerve is injured at several segments along its length, or in the case of partial brachial plexus injury.

When preoperative electrodiagnostic studies have been equivocal, or to ensure that additional recovery has not occurred between testing and surgical repair, the results of intraoperative stimulation may affect the surgical plan.

The hand-held nerve stimulator will provide information about distal motor fascicles, but will not be useful for sensory deficits. The stimulator can also be useful to confirm the identity of redundant nerve fascicles for potential nerve transfer.

Postoperative care

After tension-free primary neurorrhaphy or grafting, no immobilization is theoretically required because the extremity has been taken through full range in the operating room prior to closure. Immobilization for up to 7 days protects the coaptation as the proximal axons grow across the repair site, and the authors use this strategy. Early, protected range of motion, however, is critical for neural gliding and decreased scarring.⁶⁰ Protected range of motion is started within 72 hours for most patients.

In patients with concomitant injuries, the postoperative protocol is guided by the injury and is often difficult to rehabilitate. For example, in a zone 2 volar finger injury where both nerves and tendons are transected, the flexor tendon rehabilitation protocol takes precedence over the nerve rehabilitation, as the nerves can be readdressed at a later time if necessary. In the case of fractures in addition to nerve or soft-tissue injury, the bony fixation takes precedence.

Postoperative pain management is a critical part of the broader treatment of a patient with a nerve injury, and can dramatically affect outcome. Many patients complain in the postoperative period of paresthesia, burning, or electrical shocks. These symptoms can extend beyond the zone of injury. Most of these symptoms can be controlled with neurotropic medications such as nortriptyline, or pregabalin. In some patients, the recovering nerve pain is so severe that they require significant narcotic and neuroleptic medications and the involvement of a pain specialist becomes paramount to managing the associated chronic pain these patients experience. Anxiety and depression should also be addressed and treated.

Physical therapy and occupational therapy continue for an extended rehabilitation period to prevent joint contracture, to provide sensory and motor re-education, to fabricate and adjust splints, and to monitor progress.

Prognosis and outcomes

Prognosis

Several factors will affect the success of a nerve repair. These factors can be further subdivided into patient-related factors, injury-related factors, and repair-related factors.

Patient-related factors

The age of the patient seems to be the most predominant patient-related factor. We know from historical data that nerve repairs in children and young adults, both sensory and motor, yield better results than in adults. In part, this is due to the fact that children are smaller, and thus the nerve regeneration rate of 1 mm/day allows axons to hit the motor endplates in a shorter period of time. Children also demonstrated faster and more adaptable brain plasticity, making recovery from injury significantly faster.

Injury-related factors

The degree and type of injury affect prognosis and outcome. Proximal injuries, which often involve mixed nerves containing both motor and sensory, are more difficult to reconstruct and are located further away from target endplates. Crush and avulsion injuries are more likely to have associated soft-tissue injuries and thus tend to be worse than sharp injuries occurring at the same level. The internal damage of a nerve is often underestimated acutely and poor recovery is usually a result of repair within the zone of injury when re-explored.

Repair-related factors

The timing of repair historically revealed that earlier repair led to better prognosis, most likely because a primary neurorrhaphy was possible. Good prognosis is expected if the repair occurs within six months and the best results occur if the repair is performed within three weeks. In general, functional recovery (FR) is inversely proportional to the time of denervation and directly proportional to the number of motor axons reaching the target endplate. "Time is muscle."

$$\text{FR} \propto \frac{\text{Number of motor axons reaching target endplate}}{\text{Time of Denervation}}$$

Hints and tips

There are a number of factors affecting prognosis following nerve injury. In general, the most important factor is getting as many motor axons to the target endplate in the shortest period of time as possible.

Outcomes

The outcomes achieved with peripheral nerve repair are largely related to the prognostic factors discussed above. Sharply transected isolated distal injuries to isolated motor or sensory nerves do significantly better than more complicated injuries.

Several methods to potentially improve outcomes have been investigated. Recent interest in pharmacological therapies to augment axonal regeneration and overcome inhibitory signals has led to basic science investigation in this area.⁶¹ The role of senescent Schwann cells is another potential area to target.⁶¹

Secondary procedures

Nerve repair, either primarily or with nerve grafting or transfer, often obtains good surgical outcomes when the damage is isolated to the nerve and the injury is a clean transection. In other settings, however, a wide zone of injury or concomitant injuries make outcomes less satisfactory.

There are a number of potential secondary procedures that may improve function and can be performed at a later date. Decompression at known tight spots along the length of a recovering nerve can improve axonal regeneration, especially if re-growth has stalled. Distal nerve transfers can be performed simultaneously to supercharge or “babysit” the recovering muscles, or can be performed at a later date if grafting has failed, assuming that the nerve will reach end-target origin by approximately 12 months (Fig. 19.7).

Tendon transfers are an extremely useful adjunct to the management of significant nerve injuries, and their importance should not be overlooked. In patients who are not good candidates for lengthy nerve grafting procedures or who will not be compliant with, nor able to cooperate with, post-nerve-transfer rehabilitation, tendon transfers remain the standard of care. Certain tendon transfers, such as radial nerve transfers, are typically more successful than nerve transfers and return to activity is much faster following a period of immobilization for tendon healing.

Summary

Primary neurorrhaphy remains the gold standard for all nerve repair techniques, with autologous nerve grafting being the gold standard for bridging a nerve gap. Since the implementation of a nerve allograft in 1870 by Philipeaux and Vulpian, significant contributions regarding suturing technique, neural topography, and the biology of nerve reconstruction have transformed the way we approach nerve reconstruction. While primary neurorrhaphy and autografts are the most common methods for repair, several newer options are at our disposal. Nerve transfers have revolutionized our approach

Fig. 19.7 Algorithm for incorporating nerve transfers into the management of a nerve injury. SETS, supercharge end-to-side.

for treating devastating brachial plexus and high-level peripheral nerve injuries, converting them to lower-level injuries and allowing us to operate outside the zone of trauma. Bioengineering continues to be a long-term goal, however this is not currently an option.

This important meta-analysis pooled the international data for the treatment of C5/C6 nerve injuries and looked at recovery of elbow flexion and shoulder function assessed by MRC grade. The data strongly favored dual nerve transfers over traditional nerve grafting for restoration of both shoulder and elbow flexion. This paper has both highlighted and validated the paradigm shift away from nerve grafting in favor of distal nerve transfers and may be helpful to surgeons considering intraoperative options, particularly in cases where grafting may be suboptimal such as root avulsion, long gaps, and traumatized soft tissue.

7. Brunnell S. Nerve grafts. *Am J Surg*. 1939;44–64. This basic science paper performed in a rat model studied the potential for reverse end-to-side coaptation (now known as supercharge end-to-side (SETS)) to reinnervate distal motor endplates. Compared to negative controls, muscle-mass preservation was improved with both end-to-end and reverse-end-to-side coaptation and nerve generation across the RETS coaptation was robust. Translating this paper to the clinical setting suggests that SETS is a viable option in the treatment of nerve injury, and one that would also allow for spontaneous recovery while functioning as a babysitting procedure to keep motor endplates viable while waiting for axonal regrowth from proximal injuries.
8. Lenoble E, Sokolow C, Ebelin M, et al. [Results of the primary repair of 28 isolated median nerve injuries in the wrist]. *Ann Chir Main*. 1989;8:347–351. This basic science paper compared conduits, isografts, and several processed allografts using measurement of muscle force as an outcome. The findings that detergent-processed allografts promoted isograft-equivalent levels of motor recovery and were superior to AxiGen-processed and cold-preserved allografts suggest that the differential processing for removal of cellular constituents in preparing acellular nerve allografts does affect *in vivo* recovery. In addition, all acellular allografts promoted better motor recovery than silicone conduits. This may influence surgeons in the selection of materials to address a nerve gap.

Reconstructive fat grafting

Wesley N. Sivak and J. Peter Rubin

Access video lecture content for this chapter online at expertconsult.com 

SYNOPSIS

- Fat grafting is an important technique for tissue repair and/or augmentation in both reconstructive and aesthetic plastic surgery.
- Fat grafting can be used as a minimally invasive adjunct to restore volume and rejuvenate tissues lost secondary to aging, trauma, or disease.
- The biology and principal components of adipose tissue are reviewed with specific focus on adipose-derived stem cells.
- The safety of fat grafting – with specific focus on oncologic implications – is reviewed from both a basic science and clinical standpoint.
- Numerous aesthetic and reconstructive problems can be addressed with fat grafting, and patient selection remains vitally important.

Introduction

Autologous fat grafting has become a common technique for addressing volume and contour abnormalities in plastic surgery, demonstrating efficacy in both aesthetic and reconstructive procedures. Although early use of fat grafting was largely an aesthetic adjunct, recent advancements have made fat grafting an attractive alternative for many reconstructive challenges. A survey conducted in 2013 showed that approximately 70% of plastic surgeons have incorporated fat grafting into their clinical breast practice.¹ Fat grafting has been used successfully for facial rejuvenation, breast augmentation, mitigating radiation damage, breast capsular contracture, post-traumatic deformities, congenital anomalies, and burn injuries;^{2–8} the techniques continually evolve and novel applications rapidly emerge. Autologous fat grafts have numerous beneficial characteristics for reconstruction including: low donor site morbidity, simplicity of procedure, low cost, and resultant living autologous tissue at the site of treatment. Additionally, grafted fat has appealing bioactive factors. Cannula adipose tissue particles include adipose stem cells (ASCs) or preadipocytes, fibroblasts, vascular endothelial

cells, and a variety of immune cells.⁹ It has become apparent through extensive research in the past decade that stromal vascular fraction cells and the adipose stem cells within can improve fat graft survival, largely through their angiogenic properties.^{10,11} Applications for cell isolates from adipose tissue are also finding applications in the fields of tissue engineering and regenerative medicine. Basic science research continues to uncover cellular elements critical for inclusion in fat grafts, which will ultimately lead to modifications and enhancement of existing techniques for improved long-term outcomes.

Basic science

Adipose tissue: structure and physiology

Adipose tissue is primarily comprised of large lipid-laden adipocytes, which are surrounded by various stromal vascular cells, each with a unique role. Stromal vascular cells include fibroblasts, immune cells, pericytes, and endothelial cells. The extracellular matrix that interconnects adipocytes and forms the fat lobules within adipose tissue provides the structural framework of adipose tissue. There are two general types of adipose tissue: brown fat and white fat. In humans, brown adipose tissue is predominantly found during the neonatal period and is responsible for generating thermogenesis from triglycerides. Brown fat deposits do not appear to play a significant role in human adult metabolism, although recent research has begun to emerge on the importance of brown fat.^{30,31} The discussion here will be limited to the role of white fat, as it is used exclusively for fat grafting procedures.

White fat is involved in a variety of physiologic roles including the storage of energy-rich triglycerides,

Historical perspective

The first clinical report of fat grafting was in 1893 by German surgeon Gustav Neuber when he harvested adipose tissue from the arm and corrected a depressed facial scar resulting from osteomyelitis.¹² This was quickly followed by a report 2 years later by Vincenz Czerny, who transferred a lipoma from the buttock to correct a post-surgical breast deformity.¹³ Though state of the art for that time, fat grafting was ultimately considered difficult and too time consuming with unpredictable results.

Looking for a solution to these problems, Eugene Holländer first injected fat through a small diameter cannula.^{14,15} However, considerable reabsorption of the fat resulted. Later, in 1919, Erich Lexer published a two-volume book dedicated to the technique of fat grafting.¹⁶ In this book, he presented a wide variety of conditions such as depressed scars, breast asymmetry, knee ankylosis, tendon adhesions, and micrognathia that he successfully treated with fat grafting. Charles Miller in 1926 described the injection of autologous fat for the correction of facial folds and wrinkles.¹⁷ Despite some early favorable results, fat grafting on the whole remained unpredictable and again fell out of favor.

It was not until the 1950s, when Lyndon Peer systematically studied the gross and histologic appearance of transplanted fat, that an understanding and improved predictability of fat grafting began to emerge.¹⁸ He demonstrated adipose grafts lose about 45% of their weight and volume at one year. Fat cells that survive transfer appeared to maintain their native volume. Improper handling of the fat prior to and during transplantation decreased survival of the graft. He also demonstrated that graft size plays a role in overall survival. A graft the size of a walnut was found to lose volume more rapidly than multiple smaller grafts of similar weight, due to increased surface area of the smaller grafts. Revascularization,

seen microscopically, was noted by Peer to be essential for fat achieving graft survival.

With the advent of liposuction in the 1980s by Fournier and Illouz, there was a renewed interest in fat grafting.^{19,20} Fat was now a byproduct of a popular procedure and stood in the ready, just waiting for clinical application. Early results of grafting lipoaspirate were only partially successful; the thought at the time was that still better preparation of the fat was needed for survival. Chajchir and Benzaquen made some initial recommendations based on their own favorable results.²¹ There was still great confusion as to what really worked until the 1990s, when Coleman perfected his standard technique. This technique, called structural fat grafting, emphasizes gentle extraction of fat, centrifugation, and serial small volume injections in multiple tissue planes. Coleman has used this technique for almost 30 years and has repeatedly documented durability of fat grafting performed with his method.^{22–25} Numerous researchers have since built upon the work of Coleman and begun to lay the scientific foundation for emerging adipose technologies in the fields of tissue engineering and regenerative medicine.

Although, early reports of fat grafting by Neuber, Czerny, and Holländer as far back as the 19th century demonstrated the potential results achievable with fat grafting for facial and breast reconstruction,^{12–14} fat grafting was not widely accepted until the 1990s. Despite early successes, subsequent reports were met with varying levels of failure, often associated with unpredictable fat resorption.^{26,27} Beginning in the early 1980s, several successful reports of fat grafting were published, and fat grafting increased in popularity once again.^{20,28,29} Plastic surgeons began to recognize the importance of the technical aspects used in harvesting, processing, and injecting fat in order to achieve successful outcomes. Coleman substantiated these claims with his introduction of structural fat grafting in the 1990s, and others have since begun to lay the scientific framework and principles underlying successful fat grafting.

cushioning of vital structures and organs, maintenance of metabolic homeostasis, immune regulation, reproduction, and angiogenesis.^{32–35} The imbalance of adipose tissue resulting in either too much fat, such as in generalized obesity, or too little fat, such as in genetic or acquired lipodystrophies and aging, is an increasingly prevalent problem worldwide. Associated disorders are generally linked with physiologic derangements in insulin metabolism, triglyceride and cholesterol stores, as well as generalized insults to end organs involved in these pathways. The increased recognition of these problems has highlighted the need for a more complete understanding of adipose biology.

Adipose tissue influences metabolic homeostasis through production of assorted hormones, cytokines, growth factors, and other peptides. Factors secreted by adipose tissue are involved in a broad spectrum of physiological processes and molecular pathways including: lipid and steroid metabolism, growth factor signaling, protein binding, cytokine signal transduction, vasoactivity, eicosanoid activity, alternative complement system activation, and extracellular matrix deposition. These effector molecules, termed adipokines, exert their influences in endocrine, paracrine, and autocrine manners. Major adipokines leptin and adiponectin are implicated in obesity and function by regulating appetite and energy expenditure.^{32–35} Tumor necrosis factor- α (TNF- α), interleukin-8 (IL-8), and interleukin-6 (IL-6) are all increased in obesity; they function as proinflammatory cytokines promoting increased insulin resistance. In addition, type 1 plasminogen activator inhibitor (PAI-1) is also increased in obesity and functions to promote thrombosis by inhibiting fibrinolysis, acting as a main endogenous regulator of the coagulation system.³⁶

Adipocyte differentiation begins with the transformation of mesenchymal stem cells into adipoblasts, preadipocytes and, finally, mature lipid-synthesizing, lipid-storing adipocytes. Preadipocytes bear striking resemblance to early fibroblasts in terms of their cellular architecture and cytoskeletal arrangement. Differentiation involves the coordinated expression of specific genes involved in producing the adipocyte phenotype.³⁷ Transcriptional regulation of adipocyte differentiation during development is largely controlled by peroxisome proliferator-activated receptor- γ (PPAR- γ). PPAR- γ is the factor demonstrated to be the most specific to adipogenic differentiation. When its receptor becomes activated by its agonist ligand in a target cell, a process of differentiation into an adipocyte begins via morphologic changes, lipid accumulation, and activation of genes distinctively expressed by the mature adipocyte. Additional support during differentiation comes from CCAAT/enhancer-binding proteins (C/EBPs), with C/EBP- β and C/EBP- α specifically stimulating PPAR- γ expression during early differentiation and C/EBP- α having a similar role later in the pathway. Recently, lipoprotein lipase (LPL), specific Krüppel-like factors (KLF5, KLF15, and KLF2), early growth response 2 (Krox20), and early B-cell (O/E-1) factors have also been implicated in adipocyte differentiation.^{38–42} Both insulin and insulin-like growth factor-1 (IGF-1) are known to be required for adipocyte differentiation. Simultaneously, preadipocyte factor-1 (pref-1), whose role is in the maintenance of the preadipocyte phenotype, is decreased during adipocyte differentiation. Late markers of differentiation, which are factors produced once adipocytes mature, include adipisin, angiotensinogen II, acyl-coenzyme A (Co-A)-binding protein (ACBP), leptin, and two

fatty acid-binding proteins (FABP) known as adipocyte lipid binding protein (aP2) and keratinocyte lipid-binding protein. As preadipocytes differentiate into adipocytes, they lose their morphologic similarities to fibroblasts via decreased expression of collagen types I and III and increased production of collagen type IV, laminin, entactin, and glycosaminoglycans. In fact, inhibition of collagen synthesis during this phase actually blocks preadipocyte differentiation.⁴³

Biology of ASCs

Preadipocytes were first described in 1976 by Dardick in a rat model;⁴⁴ similar cells were later isolated from human adipose tissues.^{45–47} Isolated preadipocytes were initially used to probe adipocyte biology *in vitro*, leading to the recognition that different anatomic locations and adipose depots express different biological characteristics, such as adipocyte size and lipolytic potential. In 2001, Zuk⁴⁸ first discussed the differentiation plasticity of preadipocytes and eventually the term adipose-derived stem cell (ASC) was adopted to encompass the characteristics of self-renewal, asymmetric division, and multi-lineage potency. Although ASCs proliferate and rapidly expand in culture, exogenous growth factors are required to induce lineage-specific differentiation.⁴⁹ Differentiation of ASCs to other mesenchymal phenotypes has been well established both *in vitro* and *in vivo*. ASC differentiation to cell lineages of the ectodermal and endodermal germ layers has also been successful in several studies.^{50–68}

Adipose-derived stem cells (ASCs) are prevalent within human adipose tissue, surrounding blood vessels and residing within the connective tissue framework. These non-lipid-laden stromal cells are easily isolated from either suction-aspirated adipose tissue or excised human fat via enzymatic collagenase digestion. Numerous descriptions for cell isolation methods appear in the literature.^{69–71} The resultant freshly isolated cell pellet is highly heterogeneous and is named the stromal vascular fraction (SVF). When SVF cells are placed in culture, the ASCs adhere to the surface of an untreated tissue culture flask after 6–8 hours' incubation at 37°C and 5% CO₂. Once ASCs have adhered to the culture flask surface, non-adherent populations, representing approximately 7–15% of the SVF and consisting of mainly hematopoietic origin cells, are washed away with sterile phosphate buffered solution and/or fresh culture media. A commonly used ASC expansion medium consists of a Dulbecco's Modified Eagle Medium (DMEM) and DMEM/F12 media combination, with 10% serum, antibiotic (e.g., penicillin, streptomycin), and a small amount of dexamethasone to halt differentiation to another mesenchymal lineage. Once in culture, specific growth factors or other additives can be applied to direct the differentiation to a specific phenotype, such as adipose, bone, cartilage, or muscle.

SVF is attractive therapeutically because it may be obtained from tissue within 60–90 minutes, and the isolation can be performed in a clean room near an operating room, or even within an operating room using available automated devices. Collagenase digestion results in approximately 2–5 × 10⁵ nucleated SVF cells per gram of adipose tissue. However, complete ASC isolation takes 24 hours and requires access to cell culture facilities. Benefits of cell culture also include the ability to differentially expand the cell number, select for specific subpopulations, or control the microenvironment for

directed differentiation, or seeding of a scaffold material. Flow cytometry characterization of the surface markers on freshly isolated and cultured adipose-derived cells can be performed, and shows the presence of early progenitor markers such as CD34 and CD90.^{49,72}

Freshly isolated SVF obtained directly from harvested adipose tissue has diverse patterns of cell surface markers as identified by flow cytometry.^{50,72} Zimmerlin and colleagues identified several similar cell surface markers in ASCs compared with bone marrow-derived stem cells (BMSCs).^{72,73} Li and colleagues reported four subpopulations of interest that can be isolated and cultured.⁷⁰ The first subpopulation is CD31+/CD34- and is classified as "mature endothelial" as it expresses the endothelial marker of CD31 but lacks the progenitor marker CD34. The second subpopulation is classified as "endothelial stem" and is CD31+/CD34+, expressing both endothelial and progenitor markers. A third subpopulation, CD31-/CD34+ is classified as "adipose stem" (i.e., ASC), displaying just progenitor markers. The fourth subpopulation represents a "pericyte group" characterized by surface markers CD146+/CD90+/CD31-/CD34-. Pericytes function as contractile cells that regulate blood flow and reside adjacent to the blood vessel walls as shown by immunostaining.⁵¹ Similar to BMSCs, ASCs do not express major histocompatibility complex (MHC)-II and inhibit proliferation of activated peripheral blood mononuclear cells, suggesting a role for modulating the immune system in inflammatory disorders or allogeneic transplantation.⁵⁰ In fact, ASCs are an active target of much research in the area of vascularized composite tissue transplantation, hoping to aid in the induction of tolerance to transplanted allograft tissues.

Nonenzymatic isolation of ASCs and SVF has been a topic of recent interest, driven by a potentially less restrictive regulatory pathway. Strategies have focused on mechanical forces such as ultrasound, but there is no evidence to suggest equivalence to enzymatic digestion. There has also been interest in whether there are viable ASCs in the aqueous portion of the lipoaspirate, obviating the need to expose tissue grafts to digestive enzymes. Although some cells are present, the quantity is insufficient for clinical use. Because the ASCs are firmly embedded within the connective tissue, enzymatic digestion is currently necessary to release them in significant quantity for use in clinical applications.

Fat harvesting, preparation and grafting techniques

Over the last 30 years, numerous fat grafting techniques have been described with each iteration promising improved consistency and more reliable outcomes. To date, a standard has yet to be universally adopted by all authorities. Most variables that remain in question relate to three major steps in fat grafting: (1) harvesting from the donor site, (2) processing the fat *ex vivo*, and (3) reintroduction to the recipient site. Investigators refining the techniques of fat harvesting, preparation, and grafting have relied upon clinical outcomes in addition to utilizing both *in vitro* and *in vivo* models of adipogenesis. Lack of consensus thus far has resulted from numerous studies showing equivocal results when various methodologies are compared. In 2009, the ASPS Fat Graft Task Force published its evidence-based guidelines for autologous fat grafting based upon a thorough review of the existing literature.

Common approaches to fat harvesting include syringe aspiration and liposuction.^{25,74,75} The primary concerns during tissue harvest are minimizing the level of invasiveness (i.e., patient safety) and maximizing tissue viability (i.e., efficacy). The ASPS Fat Graft Task Force in its 2009 report suggested that tissue harvest be performed using a 3- to 4-mm blunt cannula, while utilizing minimal amounts of suction required for tissue extraction.⁷⁶ However, a 2013 report by Lee showed no statistically significant differences in parcel size or histologic architecture when fat was harvested with suction pressures up to -0.83 atm through a standard 4-mm cannula.⁷⁷ Additionally, the utilization of ultrasound-assisted liposuction also appears to have minimal effect on cellular viability and overall graft survival rates, with similar amounts of SVF cell populations present irrespective of the harvest technique utilized.⁷⁸

Once the fat has been harvested, it can be prepared for injection via one of several methods, which can include washing with physiologic buffers, centrifugation (for separation of cells from debris), decantation, or concentration (i.e., rolling across an absorbent medium).^{28,79-83} To avoid contamination and maximize tissue viability, exposure to air and mechanical damage should again be minimized. The ASPS Fat Graft Task Force in its 2009 report suggested that viable adipocytes be separated from blood, serum, and damaged adipocytes via centrifugation (3000 rpm for 3 minutes) while remaining within the harvest syringe to limit exposures.⁷⁶ However, Fisher *et al.* demonstrated superior graft retention rates with gauze-rolled fat, attributed in part to greater retention of the SVF components.⁷⁸ In a 2012 review of fat grafting techniques, Gir and colleagues concluded the body of evidence to date does not support one processing technique above another.⁶ They do, however, caution that when centrifugation is used, several studies suggest that forces greater than 3000 rpm (1200 g) can inflict greater levels of cellular damage that can negatively impact overall graft retention rates.

Once refined, fat is subsequently injected subcutaneously with an assortment of delivery methods using blunt-tipped needles. To optimize fat graft viability, mechanical damage of the tissue must be minimized during the injection process. The ASPS Fat Graft Task Force 2009 report suggests that injection be performed using a 2- to 2.5-mm blunt-tipped infusion cannula (or a similar blunt needle); small aliquots of fat should be deposited serially, with multiple injections occurring in multiple tissue planes within the area of augmentation.⁷⁶ Ozsoy *et al.* compared three different diameters of injection Coleman-type cannulas and found that adipocyte viability was significantly greater with 2.5-mm-diameter injection cannulas compared with smaller diameter cannulas (1.6 or 2 mm).⁸⁴ Adipocytes have been shown to be highly susceptible to the effects of shear stress, which is proportional to flow rate during injection. Lee *et al.* demonstrated that slow injections (0.5–1 cc/second) resulted in a 38% improvement in fat graft survival over fast injections (3–5 cc/second) through similar sized cannulas.⁷⁷ Special consideration should be made to minimize the factors that increase shear stress upon the graft. Variables such as viscosity, concentration, cannula length, cannula diameter, and flow rate play a significant role and can negatively impact fat graft survival to a high degree when proper technique is not utilized.

Another variable to consider in the overall technique of fat grafting is the ideal donor site. When harvests from four

commonly used donor sites (abdominal fat, thigh fat, flank fat, or knee fat) from five subjects were evaluated, no immediate differences in adipocyte viability were observed.⁸⁵ These results were corroborated by another study in which no differences in fat viability were observed when fat was harvested from three donor sites from one subject (thigh, abdomen, and breast) and injected into a nude mouse model.⁸⁶ However, these results were challenged by Schipper *et al.*, showing there is variability in physiologic function of ASCs that have been harvested from different subcutaneous depots, with the superficial abdominal depot being most resilient and providing superior graft retention rates.⁸⁷ Additionally, the authors demonstrated age-related changes in ASC function that may impact overall graft survival irrespective of depot used, stressing the importance of appropriate patient selection. Furthermore, ASC counts in harvested tissues are observed to vary widely from patient to patient and not only from depot to depot.

Published data thus far have failed to produce an agreed-upon algorithm of the required components for successful, consistent, and durable autologous fat transplantation. There is a modest preference in favor of the following approach: harvesting abdominal fat with a blunt-tip cannula technique, centrifugation without washing or other manipulation, and immediate injection of small aliquots of fat by means of multiple passes.⁷ After almost 30 years of varying applications of fat transfer, surgeons and scientists alike are attempting to provide insights into fat grafting techniques so that patients are provided with optimized clinical outcomes. Large, well-designed prospective randomized clinical trials are needed but remain elusive given the sheer number of variables in question and difficulty with appropriately blinding surgeons.

Safety concerns

The overall safety of fat grafting procedures is well established, with low morbidity and relatively few perioperative complications. Overall, patients tolerate the procedure exceedingly well. However, when questions regarding the safety of fat grafting arise, they are generally related to oncologic matters. The presumed interactions of fat grafts with the recipient tissues are of primary concern – either the ability to scar and distort cellular architecture or the ability of progenitor cells to push and/or accelerate aberrant processes. Breast cancer-related defects remain by far the most common oncologic defects reconstructed with autologous fat.⁸⁸ With breast cancer being the most common cancer in females and the leading cause of cancer-related death in females, in 1987 the ASPS banned fat grafting to the breast primarily due to concerns regarding ongoing cancer surveillance. This was presumed to be due to low graft retention rates and high rates of fat necrosis that were believed to interfere with routine cancer surveillance. Concerns were later raised about the interaction of ASCs within the fat graft and residual microscopic disease that may remain following extirpation.

In 2007, the ASPS established its Fat Graft Task Force to re-examine the potential hazards and numerous benefits of fat grafting to the breast. During the 1990s, Coleman had introduced and refined the concept of structural fat grafting, leading to increased retention rates and better understanding of graft predictability. In the decades since, there had also

been significant advances in cancer screening technologies through the development of advanced mammography, MRI, and ultrasound techniques. Given the lack of quality data implicating autologous fat transfer, it is surprising that concerns continue to persist.

Concerns regarding oncologic risk of fat grafting are primarily four-fold: (1) interference with cancer surveillance, (2) growth factor release, (3) stem cell malignant transformation, and (4) enhanced migration and metastases of cancer cells. Despite these concerns, fat grafting has become routine in breast cancer reconstruction. This is due to the ability to reliably transfer autologous tissues without the need for microsurgery, simple outpatient-based procedures, and abundance of donor sites with minimal morbidity. Despite the aforementioned concerns, the number of articles in the literature examining fat grafting has steadily risen since the early 1990s as practitioners continually refine and expand upon the technique and its indications.¹

The concerns related to interference with cancer surveillance have by and large been resolved in the literature, with no studies demonstrating evidence of impediment to breast cancer screening or surveillance in patients undergoing fat grafting procedures. A matched cohort analysis of patients undergoing post-mastectomy breast reconstruction with and without fat grafting as a secondary procedure found the incidence of breast biopsy to clarify abnormal imaging was not significantly higher in the fat-grafted group (17.6% versus 7.8%, $p=0.14$).⁸⁹ In fact, fewer than 10% of imaging studies in the fat-grafted cohort were performed to investigate a clinical or radiographic abnormality occupying the same breast quadrant as prior fat injection. Another study by Rubin *et al.* examined mammograms from patients undergoing either breast fat grafting or breast reduction procedures and found scarring ($p<0.001$) and masses requiring biopsy ($p<0.001$) were significantly higher in the breast reduction cohort.⁹⁰ In addition, BI-RADS scores were noted to be significantly higher for breast reduction patients ($p<0.001$). Finally, a 2015 systematic review of fat grafting to the breast that included 35 studies with 3624 patients found fat necrosis was the most common complication (4.4%), biopsy of a subsequent breast lump was required in 2.7% and an interval mammogram in 11.5% of patients.⁹¹ Meta-analysis of comparative studies showed no significant difference in oncological event rates between fat-grafted and non-fat-grafted groups ($p=0.10$).

Currently, a discrepancy exists in the literature surrounding fat grafting and breast cancer. Basic science studies repeatedly demonstrate a strong interplay between ASCs and cancer cells. However, clinical studies fail to demonstrate any significant detrimental effect with one lone exception. *In vitro* experimental models show ASCs can create an enhanced environment promoting tumorigenesis. And yet recurrence rates amongst patients who have had fat grafting after cancer treatment parallel those who have not. This discrepancy exists in large part due to the use of immortalized breast cancer cell lines (BCCs) used to represent primary or recurrent breast cancer in laboratory studies.

Immortalized cell lines are routinely used as surrogates in the laboratory to probe the biologic behavior of various tissue types. One must recall that BCCs utilized today were isolated decades ago from distant metastases and remain phenotypically different from primary cancer cell lines. Great caution must be exercised when interpreting studies utilizing them as

representatives of primary cancer. However, multiple studies do demonstrate strong interactions between BCCs and ASCs. In a study assessing the role of the PDGF- β signaling pathway in cancer metastasis, conditioned medium from MDA-MB-231 and 4T1 BCCs was shown to serve as an attractant via chemotaxis for ASCs.⁹² In another study, *in vitro* migration of triple-negative MD-MB-231 was enhanced by ASC co-culture; similar results were also achieved with ASC conditioned media.⁹³ In the study, increased metastases were also seen in the liver, lung and spleen in a murine xenograft model, suggesting a role for ASCs in angiogenesis and overall increase in metastatic potential of BCCs. In yet another study, intercellular contact between ASCs and BCCs led to increased expression of malignancy markers in BCCs.⁹⁴ Specifically, ASCs with higher basal levels of hepatocyte growth factor led BCCs in co-culture to increase expression of c-Met, suggesting a role for ASCs in enhancing tumorigenesis. When co-injected with BCCs into nude mice, ASCs were found to differentiate into endothelial-like cells and supported development of larger primary tumors.⁹⁵ CD34+ progenitor cells from fat have been shown to differentiate in endothelial cells and form capillaries that supported tumor growth and metastasis.⁹⁶ Interestingly, ASCs can also promote progression and penetration of the invasive BCC line T4-2, but not its pre-invasive variant HMT-3522-S3, suggesting pre-invasive lesions may not be as sensitive to the local effects of ASCs.⁹⁷ Experimental results like those above should be interpreted with great caution – as the experimental scenarios are highly idealized and do not represent any realistic clinical setting. BCCs again are not representative of clinical malignancies and ASC doses used in the experiments are orders of magnitude higher than could ever be obtained in clinical situations. Nonetheless, caution with cell-enriched therapies is certainly warranted in high-risk patients with breast cancer.

So what exactly is the clinical risk of fat grafting to the breast? Breast cancer recurrence rates are in the range of 5.2–10.6% in patients who have not undergone fat grafting after breast cancer surgery.^{98,99} A systematic review examining the oncologic safety of breast fat grafting reviewed 16 clinical studies including 2100 patients and found a local recurrence rate of 2.2% following fat grafting procedures.¹⁰⁰ A case-control study assessing the oncologic safety of fat grafting reported no significant excess oncologic events in patients after fat grafting with respect to local recurrence (0.95% vs 1.90%, $p=0.33$), regional recurrence (0.95% vs 0%, $p=0.16$), and distant recurrence (3.32% vs 2.61%, $p=0.65$).¹⁰¹ A concurrent systematic review of the literature in the same study identified 1573 women who had fat grafting after oncologic breast surgery and found a loco-regional relapse rate of 2.92% (or 0.95% per year). Another systematic review of the literature included 35 studies and 3624 patients and found a 4.4% weighted mean recurrence rate at 24.6 months amongst patients who underwent autologous fat grafting of the breast.⁹¹ Meta-analysis in that same study showed no significant difference in oncologic event rate between fat-grafted and non-fat-grafted groups. A matched-cohort study assessing loco-regional risk after fat grafting in 321 breast cancer patients and 642 matched controls found no difference in recurrence between fat grafting and control groups ($p=0.792$).¹⁰² However, when cases were limited to intraepithelial neoplasia ($n=37$), fat grafting may have caused 4 recurrence events ($p<0.001$). A subsequent study by the same authors, which looked specifically at 59 patients

with intraepithelial neoplasia compared to 118 matched controls, showed the 5-year local recurrence was 18% versus 3% for fat grafting and controls, respectively ($p=0.02$).¹⁰³

Many systematic reviews/meta-analyses demonstrate similar loco-regional recurrence rates for breast cancer patients who underwent fat grafting relative to control subjects. Yet one case series and one clinical study (both from the same group of authors) point to higher local breast cancer recurrence after fat grafting in patients with intraepithelial neoplasia. In a 2015 review, the authors of the two studies in question showing increased rates of recurrence state that definitive conclusions require large series, controls with matching cancer criteria, and minimum 5-year follow-up.¹⁰⁴ However, the oncologic safety of fat grafting has already been proven in the literature and overwhelmingly demonstrates the overall safety of fat grafting procedures in breast cancer patients.

Diagnosis/patient presentation

While the aesthetic applications of fat grafting have long been described, this technique has numerous reconstructive applications. These include congenital deformities such as hemifacial microsomia and Treacher Collins syndrome. In addition, patients who have sustained previous trauma resulting in significant scarring or tissue loss can often benefit from fat grafting.¹⁰⁵ Patients who have undergone previous cosmetic surgery can also present with iatrogenic deformities such as hollowed upper eyelids, flattening of the posterior jaw line, or contour deformities resulting from liposuction. These areas can be restored to a more youthful and natural appearance with thoughtful and sensible applications of fat grafting.

A newer use of fat appears to come from its regenerative properties on damaged tissues. Rigotti has grafted fat beneath tissue ulcerations in the breast that occurred after radiation therapy, and has noted remarkable restoration and healing of the involved tissues.¹⁰⁶ Irradiated tissue that is stiff and non-compliant can be restored to a more normal consistency and texture and allows filling of contour deformities. In addition, anecdotal reports have been made regarding the improvement of the appearance of scars and skin quality after fat grafting.^{5,105} Amputees with poorly fitting prosthetics also appear to gain benefit from remodeling of the stump at the prosthetic interface, providing more robust tissue coverage and a better, more durable fit.¹⁰⁷

Patient selection

Patient selection must begin with a detailed history, noting pertinent medical comorbidities that may limit therapeutic potential. Candidates must be able to withstand the anesthetic requirements of the procedure, and as a result it may not always be prudent to offer fat grafting to those with profound systemic ailments. Fat grafting to small areas can certainly be performed under local anesthesia, but anything involving more than a few milliliters will generally require sedation at a minimum. Physical examination entails a thorough assessment of the defect in question in addition to assessment of potential donor sites. This allows the physician to formulate a plan for correction of the defect in question. Patients with unrealistic expectations are not good candidates for this or

Fig. 20.1 Large volume fat harvest and processing represents a logistical challenge in the operating room. A simple apparatus consists of a sterile collection chamber set up in-line on the sterile field. Machine-generated suction from a standard liposuction aspirator is applied through the system, and a standard liposuction cannula of 3 or 4 mm diameter used to harvest fat into the vessel (A). The aspirate is allowed to decant until the fat separates from the aqueous layer. The aqueous layer is then removed by aspiration with a suction cannula (B,C). Commercially available vessels for large-volume fat collection are also constructed with spigots at the base to drain the aqueous layer.

any other procedure. Patients must be informed that several rounds of fat grafting may be needed to achieve the desired results.

A relative contraindication is the thin patient who does not have sufficient fat stores from which to harvest fat. Since large volumes of fat are generally not needed for the face, enough fat can usually be harvested for these procedures. For fat grafting to the breasts or body, significantly more fat is generally required; often there is a limit to the correction that can be made given the paucity of fat in some patients. Asking the patient to gain weight prior to the procedure is feasible only if the patient is willing and able to maintain that weight afterwards. Weight loss following fat grafting can lead to loss of volume and failure to maintain adequate correction.

Treatment/surgical technique

The surgeon must be familiar with the potential levels of placement (e.g., subdermal, intramuscular, and supraperiosteal) and the amounts necessary at each level to accomplish a desirable change. These amounts will vary across regions of body as well as from patient to patient. Determining the amounts of fat to place and the levels in which to place the fat in order to create subtle, lasting contour changes requires a sophisticated surgical plan.

The Coleman method of fat grafting remains essentially unchanged since the original inception almost three decades ago.²⁴ The process relies upon harvesting the fat gently to preserve its architecture, refining the fat with centrifugation to remove nonviable components and provide a predictable volume, and placement of the fat in small aliquots to increase the surface area and ensure a robust blood supply to the grafted tissue.²³ When these principles are adhered to, fat grafting can be a reproducible and safe procedure. Histologic studies have shown that this method of harvesting and refinement with centrifugation yields fat with a high percentage of survival and near-normal adipose cellular enzyme activity¹⁰⁸ and, for small volume grafting, filtering the fat on sterile

gauze (Telfa rolling) can result in even higher rates of retention of injected fat. However, this method lacks efficiency. In the case of large volume fat injection, the principles of harvest and injection must be adapted to enable greater volumes of fat to be handled efficiently in the operating room (Figs. 20.1–20.6).

Harvesting

As no conclusive differences in viability or graft take have been demonstrated from one site to another in scientific studies, the choice of donor site for fat grafting is dependent on the desires of the patient and accessibility of the fat. In general, the abdomen, “love handle”, posterior hip, back, and lateral thighs are useful sites. In thinner patients, especially males, the medial thighs are an often overlooked but fruitful depot. Incisions should be hidden in creases, scars, stretch marks, or hair-bearing areas, if at all possible. Through these incisions, local anesthetic solution is infiltrated using a blunt

Fig. 20.2 An alternative to decanting the fat is to filter the fat in a medical grade sterile sieve.

Fig. 20.3 The sterile graft material can be handled by placing it in a vessel with a pour-spout (A), and then filling capped 30-cc syringe barrels from the back (B,C).

infiltration cannula. The local anesthetic mixture should consist of 0.2% lidocaine with 1:200 000 epinephrine. In general, the amount of solution infiltrated is equal to the amount of fat removed (1:1 ratio, superwet technique).

After waiting approximately 10 minutes for the local anesthetic solution to take effect, fat is then harvested using a bucket-handle harvesting cannula. This harvesting cannula is designed to harvest intact fatty tissue parcels that are large

enough to survive, but small enough to pass through the standard 17-gauge infiltration cannula used for grafting. The cannula may be utilized with any vacuum- or power-assisted liposuction equipment or simply attached to 10-ml syringes. If 10-ml syringes are used, the plunger is pulled back only a few milliliters so as not to create too much negative pressure and traumatize the aspirate. Incisions are closed with interrupted 5-0 fast-absorbing sutures.

Fig. 20.4 For large-volume fat grafting, a 16-gauge blunt-tipped cannula can be used with the 30-cc syringes (A), and the fat should be easily flowable (B).

Fig. 20.5 For small-volume fat grafting, the Coleman processing method is highly efficient and reproducible. A tabletop centrifuge (A) with a sterile rotor and tubes, holds 10-cc syringes (B) and generates 1200 G-force at 3000 rpm. The fat is centrifuged for three minutes to separate the oil, fat, and aqueous layers. After draining the aqueous layer and wicking the oil with cotton gauze, the fat can be filled into 1-cc syringes (C), using a Luer connector or by filling the syringe from the back. Blunt-tipped cannulas with a very small aperture and diameter are fitted to the 1-cc syringes for precise placement of fat in the regions such as the face or hand (D,E). These blunt-tipped cannulas also come in curved shapes for accessing tight spaces.

Refinement

As fat is harvested, the first few passes of the cannula will retrieve more local anesthetic than subsequent passes. As suctioning continues, the later passes may contain less aspirate and more blood. After harvest, lipoaspirate is transferred to 10-ml syringes; a Luer-Lok™ plug is used to cap the syringe. Using 10-ml syringes for aspiration avoids the need to transfer. The plunger is removed, and the syringe is placed into a sterile centrifuge. It is vitally important to maintain

sterility during the centrifugation process – a centrifuge with a sterile central rotor and/or sterile sleeves is essential. Centrifugation at 3000 rpm (1200 g) for 3 min concentrates the fat so that the aqueous components (the local anesthetic and blood) can be removed and discarded by releasing the Luer-Lok™ plug. In addition, any oil can be decanted off the top and/or wicked away with gauze pads. The processed fat is then transferred to a 1-cc syringe for placement into the defect.

Placement

Planned incision sites are anesthetized with 0.5% lidocaine with 1:200 000 epinephrine and small stab incisions are made for the placement of fat through 17-gauge Coleman injection cannulas. This not only helps to reduce bruising, but also decreases the chance of accidental intravascular embolization of the fat. The success of the fat grafting procedure depends not only on the harvesting and refinement, but also on the placement of the fat in a manner that increases its chance for optimal survival. This means maximizing the contact surface area of the fatty parcel with the surrounding tissue, such that a blood supply can be conferred to the newly grafted fat. Transferring large globules of fat can result in central necrosis of the mass with subsequent resorption and loss of volume, or possibly even cyst formation.

The fat is gently placed during the withdrawal of a blunt Coleman infiltration cannula. Recall fat can be placed at different levels to accomplish different effects – determining where and at what level to place fat relies upon the skill and experience of the surgeon. For instance, grafting fat

Fig. 20.6 For processing very small volumes for grafting, an easy method is filtering the fat graft on Telfa non-adherent gauze. This method yields a high retention rate, but lacks efficiency.

Fig. 20.7 Head and neck cancer reconstruction using fat graft. This 57-year-old woman was treated for an aggressive squamous cell carcinoma with full-thickness cheek resection and reconstruction with a radial forearm free flap and subsequent radiation therapy. She presented three years after her cancer reconstruction, disease free, desiring further reconstruction, this time with fat grafting.

immediately beneath the dermis can improve the quality of the skin, decrease wrinkling, decrease pore size, and may even reduce scarring. Special care must be taken, however, when placing fat superficially, as surface irregularities are more apt to be apparent. This is especially true in areas that have thin skin, such as the lower eyelid. To make changes in the shape of the body that relate to the underlying bony skeleton, fat can be placed above the periosteum. To build bulk, the fat can be placed intramuscularly. The structure should be purposefully built up with tiny aliquots of fat rather

than attempting to insert larger aliquots and then mold the tissue after it is placed. Molding may displace the fat or cause necrosis of some or all of the fat in an area, decreasing predictability and increasing uneven contours. The only time molding should be considered is if an irregularity is noted at the time of placement, as the surface must be smooth before leaving the operating room. The stab incisions used for placement of the fat can be closed with single interrupted 5-0 fast-absorbing sutures. An example of small volume grafting to the face for reconstruction is shown in Figs. 20.7–20.10. Large-volume

fat grafting to the breast is shown for lumpectomy defects (Fig. 20.11), replacement of implants (Figs. 20.12–20.14), and total breast reconstruction (Fig. 20.15).

Postoperative care

Care of the patient after fat grafting remains relatively simple. Grafted areas are not routinely dressed, and patients may shower 48 hours following the procedure. If possible, grafted

areas should remain elevated above the level of the heart for 72 hours following the procedure. Direct pressure upon the grafted area should be avoided for one week. Sutures in the face are removed in 4–5 days, and resorbable sutures at other sites can be removed in one week or left to dissolve away on their own. Donor sites may be dressed with compression garments or an abdominal binder if large volumes are harvested. Deep massage is avoided for one month postoperatively. Preoperative antibiotics will suffice for most patients, while those patients that are at high risk for surgical site infection can be given 3–5 days of antibiotics postoperatively.

Outcomes, prognosis, and complications

Fat grafting procedures by and large are deemed to be low risk and are associated with low perioperative morbidity rates given proper patient selection. Soreness and swelling are common, but not every patient will experience them. The most significant risk remains the unpredictable nature of the graft, where the recipient site may simply reabsorb most of the transferred fat. The extent of resorption at this time cannot be predicted for a given individual, but some degree of resorption will happen in every patient. Rare but possible fat transfer risks and complications include: allergic reaction to the local anesthetic, permanent discoloration caused by a ruptured blood vessel, fat necrosis, oil cyst formation, calcification, overcorrection, perioperative bleeding, a blood clot at the treatment or donor site, a blood-borne infection (more likely if combined with another cosmetic procedure), scarring, and a fat embolism from direct fat injection into a blood vessel. Most problematic is the high potential for contour irregularities visible through the skin, which can occur in both the recipient and donor sites. In the recipient sites, excess grafted fat will appear as lumps beneath the skin, and is generally the result of placement of a volume that was too large just beneath thin skin. Unwanted parcels of fat can be difficult to remove at a later time, therefore prudence should be exercised when placing grafts. Potential remedies for irregularities caused by excess fat include liposuctioning of the fat, direct excision, lipodissolve products (not approved by the FDA in the United States), and potentially off-label use of the deoxycholic acid derivative ATX-101 (known as Kybella®).^{109–111}

Irregularities in the donor sites can be pronounced, particularly if too much fat is removed from a single area. Significant changes in weight can also result in related changes in the size of the area grafted, therefore patients are encouraged to have fat grafting procedures performed when they are at their ideal body weight and to maintain that weight indefinitely.

Secondary procedures

With fat grafting, secondary procedures, or touch-up procedures, are possible if an incorrect volume of fat was placed initially. Infiltration and swelling at the time of surgery, in addition to the unpredictable resorption of fat, make

achieving perfection in a single stage difficult. Patients should be instructed that multiple rounds of grafting might be required to achieve the desired end. In reconstructive cases, the soft tissue envelope often limits the surgeon, and as tissue quality improves after initial fat grafting, the area may become more receptive to larger subsequent volumes. It is far better to under-correct a deficient area and return to the operating room for a second stage, if necessary, at a later date. In complicated liposuction cases, a second stage is often part of the original plan, as it can be very difficult to make an area perfect in one procedure. Generally, the goal of the first procedure is to fill in large defects with significant amounts of fat and later to come back and refine the area with additional grafts.

Vascular territories

Steven F. Morris and G. Ian Taylor

▶ Access video lecture content for this chapter online at expertconsult.com

SYNOPSIS

- This chapter provides an overview of the angiosome concept and reviews the vascular anatomy of the body. The historical perspective summarizes the major progress in understanding the vascular basis and clinical applications of flaps in reconstructive surgery.
- The anatomical basis of angiosomes, choke anastomotic vessels, arterial territories, and venous drainage of the human body are summarized. The neurovascular territories of skin and muscle are described. Comparisons with other species highlights the consistent features of vascular anatomy of the human body and illustrates the need to be aware of the vascular anatomy of animal flap models.
- The vascular anatomy of skin, muscle, and bone of each region of the body is discussed with an emphasis on flap design, avoiding surgical complications and providing an overview of angiosomes of the body.
- The general concepts of the vascular supply to tissues of the body are reviewed. The importance of these concepts to flap design is highlighted with clinical examples. These concepts also provide the basis for interpreting physiologic and pathologic events in skin flaps.
- The overall architecture of the vasculature of the human body is consistent but there is significant variability in individual perforator anatomy. Therefore, a versatile operative plan is needed for successful flap design.
- Methods of preoperative assessment of vascular anatomy and types of flaps, including skin, fasciocutaneous, musculocutaneous and perforator flaps, are reviewed.
- The anatomic basis of the delay phenomenon and procedure is explored.

Introduction

The angiosome theory has become well accepted in the field of plastic and reconstructive surgery and allows the conceptualization of the vascular supply to all tissues of the human body. An angiosome is a composite block of tissue supplied

by a main source vessel. The adjacent angiosomes are linked either by reduced-caliber choke anastomotic vessels or vessels without reduction in caliber – the true anastomoses of adjacent arterioles. The latter are seen in many muscles or in the skin, especially where vessels accompany cutaneous nerves. Flaps designed along an axis of vessels linked by true anastomoses have a longer survival length similar to a flap that has been delayed. The anastomotic arteries are matched by veins devoid of valves that allow bidirectional flow. The entire human body consists of innumerable arcades of interconnecting vessels which supply all tissues.

In 1977, Converse¹ stated that “there is no simple and all-encompassing system which is suitable for classifying skin flaps”. It is now generally agreed that the anatomical vascular basis of the flap provides the most accurate approach for classification. Specific, anatomically based nomenclature simplifies communication between surgeons and allows for the advancement of the field of plastic and reconstructive surgery. The main named source vessels throughout the body provide a useful road map for the description of flaps.

The vascular architecture of the body is arranged anatomically as a continuous series of vascular loops, like the tiers of a Roman aqueduct, that increase in number while their size and caliber decrease as they approach the capillary bed (Fig. 21.1). The reverse situation occurs on the venous side. This anatomic arrangement of the vascular “skeleton” is shown beautifully in the corrosion cast studies of newborn babies performed by Tompsett² that reside in the Hunterian Museum at the Royal College of Surgeons in London (Fig. 21.2). Note how the main arterial loops hug the bony framework and the secondary arcades follow the intermuscular and intramuscular connective tissue framework. The “keystones” of these arcades are represented usually by reduced-caliber (choke anastomotic) arteries and arterioles, matched on the venous side by avalvular (oscillating) veins that permit bidirectional flow. Choke arteries and avalvular veins have an essential role in controlling this pressure gradient across the capillary bed (see Fig. 21.1).

Fig. 21.1 Schematic representation of the arterial supply and venous drainage of the capillary bed. Note the choke arteries (small black arrows) and bidirectional avalvular veins (small shaded arrows) that allow equilibration of flow and pressure to the capillary bed from arterioles (red arrows) and from the capillary bed through venules (blue arrows).

Vascular anatomical research

Angiosome

The angiosome (from the Greek *angeion*, meaning vessel, and *somite*, meaning segment or sector of the body derived from *soma*, body) is defined as a composite block of tissue supplied by a main source artery. The source arteries (segmental or distributing arteries) that supply these blocks of tissue are responsible for the supply of the skin and the underlying deep structures. When pieced together like a jigsaw puzzle, they constitute the three-dimensional vascular territories of the body. In this section we present the basis of the anatomical studies which are the foundation of the angiosome concept.

The angiographic studies produced by Salmon using lead oxide, gelatin, and water were exceptional; however, modifications of the technique have further improved results.^{41,42} In particular, reducing the concentration of lead oxide has improved computed tomographic (CT) angiographic anatomic studies.⁴³ A review of vascular injection techniques reveals the wide array of techniques available for investigation.⁴⁴

Initially, cadaver injection studies to study the vascular anatomy of the human integument and other structures utilized intra-arterial injections of radiopaque substances such as barium sulfate or lead oxide or visible substances such as

latex and ink. Depending on the specific study, the area of tissue of interest was then dissected and radiographed. As the radiographic film quality improved, the quality of the image of the small blood vessels improved. However, studies using simple radiographs have largely been replaced by CT techniques.^{43,45,46} These investigations were conducted in fresh cadavers. In the majority of studies, the anatomical question was problem-oriented in a desire to provide a surgical solution to the individual patient's needs. We have performed a large number of fresh cadaver studies, investigating various regions, tissues, and combinations of tissues. This has included an investigation of the entire integument and underlying deep structures in a series of total body studies of the arteries,⁴⁷ which led to the angiosome concept, discussed in detail in a later section. This was followed by studies of the veins⁴⁸ and the neurovascular territories of the body⁴⁹ and detailed studies of the angiosomes of the forearm,⁵⁰ the leg,⁵¹ and the head and neck,⁵² as well as a comparative study of a series of mammals.⁵³ As well, we have performed detailed analyses of numerous muscle flaps including sartorius,⁵⁴ rectus femoris,⁵⁵ gracilis,⁵⁶ pectoralis major,⁵⁷ and skin flaps, including the reversed sural artery flap,⁵⁸ thoracodorsal artery perforator

Fig. 21.2 Tompsett's arterial skeleton of the body. This corrosion cast of the newborn body shows the arterial architecture of the body. (From Taylor GI, Palmer JH. *The vascular territories [angiosomes] of the body: experimental study and clinical applications*. Br J Plast Surg. 1987;40:113.)

Historical perspective

Plastic surgery evolved as a specialty in Europe and North America to restore the mutilated victims of the two World Wars. With artistic flair and geometric precision, tissues were advanced and rotated. These random flaps were transposed locally and dispatched to distant sites on limb carriers, only to be rebuffed on occasion by necrosis. Gillies often lamented that “plastic surgery is a constant battle between blood supply and beauty”.³ Gradually, rigid length-to-breadth flap ratios were calculated for different regions of the body because most of the flaps were designed without a precise knowledge or appreciation of the vascular supply of flaps. The flaps designed were “random” since it was not appreciated that the vascular supply was crucial to flap survival and there was little understanding of the anatomy of the underlying vasculature.

Unfortunately, this anatomic information was available but overlooked. In 1889, Manchot⁴ performed the first examination of the vascular supply of the human integument. His treatise, *Die Hautarterien des menschlichen Körpers* [*The Cutaneous Arteries of the Human Body*], was initially published in German and later translated to English.⁵ Manchot identified the cutaneous perforators, assigned them to their underlying source vessels, and charted the cutaneous vascular territories of the body (Fig. 21.3). He did not have the advantage of radiography since Röntgen was not to make his discovery until several years later. Nevertheless, the accuracy of Manchot's work has mostly stood the test of time.

In 1893, Spalteholz⁶ published an important paper on the origin, course, and distribution of the cutaneous perforators in adult and neonatal cadavers. He performed arterial injections of gelatin and various pigments. The soft tissues were fixed in alcohol and subtracted in xylol, and the resulting vascular network was embedded in Canada Balsam. Spalteholz's main study concentrated on the detailed circulation of the skin. He made an important distinction between direct cutaneous vessels, which supply the skin, and indirect cutaneous vessels, which are terminal branches of vessels supplying the deeper organs, especially the muscles. A detailed account of this work was published by Timmons⁷ in a review of the landmarks in the anatomic study of the skin's blood supply.

The next major study was performed by Salmon,^{8,9} a French anatomist and surgeon in the 1930s. Manchot had defined approximately 40 cutaneous territories that excluded the head, neck, hands, and feet. Salmon knew of Manchot's studies and set out to reappraise his work. Aided by radiography, he was able to delineate the smaller vessels of the cutaneous circulation and charted more than 80 territories encompassing the entire body (Fig. 21.4). Salmon noted the interconnections that exist between perforators, and his observation of the density and size of the vessels in different regions of the body led him to define what he called the hypervascular and hypovascular zones. His work has become available in English.¹⁰ Ironically, in the preface to Michel Salmon's book on the cutaneous vascular anatomy published originally in 1936,⁸ Raymond Grégoire stated: “This new work by Michel Salmon is a painstaking study that no surgeon from now on can ignore and few anatomists would have had the courage to undertake.” Indeed, if we had heeded this advice, plastic surgery would have evolved much earlier!

In 1975, Schafer¹¹ published an important study on the arterial and venous anatomy of the lower extremity. Scribtor and an ink-serum mixture were injected into the lower limbs of adults and into the entire circulation of fetal and neonatal cadavers. Schafer concluded that most cutaneous arteries emerge in rows from the intermuscular septa or occasionally from the intramuscular septa. In addition, he highlighted the two systems of perforating veins: the venae communicantes, large veins that pierce the deep fascia and connect the superficial venous plexus to the deep venous system; and the venae comitantes, small, usually paired veins that accompany the cutaneous arterial perforators.

Early last century, advances on the clinical front gave significance to the work of these great anatomists. In 1906, Tansini¹² reported a latissimus dorsi flap supplied by the thoracodorsal artery. In 1919, Davis¹³ published *Plastic Surgery* and introduced many of the chapters with illustrations from Manchot's book. In 1921, Blair¹⁴ described a forehead flap based on the superficial temporal vessels, and in 1929, Esser published *Artery Flaps*.¹⁵ In 1937, Webster¹⁶ again cited the work of Manchot when he described a long, bipedicle thoracoepigastric flap based on named arteries that extended from the groin to the axilla. Shaw and Payne¹⁷ used the clinical information available in wartime to provide one-stage direct flaps for hand reconstruction. In 1965, Bakamjian¹⁸ drew attention to the long paramedian perforators of the internal thoracic system.

The 1970s witnessed the beginning of the “anatomic revolution”. McGregor and Morgan¹⁹ differentiated between large flaps based on a known axial blood supply and those based on random vessels. Daniel and Williams²⁰ reappraised the work of Manchot and others and classified the cutaneous arteries into direct cutaneous and musculocutaneous vessels.

Studies on the free flap by Taylor and Daniel^{21,22} were published in 1973, and a few years later the musculocutaneous flap was revived by McCraw^{23–25} and Mathes and Nahai.²⁶ Both procedures demanded a precise knowledge of the vascular supply of the tissue transfers. In the search for new donor sites for tissue transfer, surgeons returned to the dissection room. In the 1980s the pedicled musculocutaneous flap and the free microvascular transfer gained popularity and their use became common. However, on occasion there was a tendency for the techniques to neglect the aesthetic side of plastic surgery. The results could sometimes be what McDowell²⁷ described as “globs and blobs”.

To escape from the hamburger of muscle and skin, surgeons soon rediscovered that blood vessels follow fascial planes and, starting in the 1980s, there was a much greater awareness of the fasciocutaneous flap.²⁸ With this development, there has been an explosion of new terms and new classifications of the cutaneous circulation. The thesaurus of flaps now includes a bewildering array of terms including axial, random, direct cutaneous, musculocutaneous, fasciocutaneous, supercutaneous, septocutaneous, chimeric, retrograde, antegrade, and perforator. Indeed, there has been an attempt to classify flaps into no less than 10 types and subtypes on the basis of the origin of the cutaneous perforators.²⁹ In many ways, these flap classification terms are simply different expressions of the basic cutaneous architecture that Manchot published in 1889⁴ and Salmon reported in 1936.⁸ In an effort to standardize the literature and add clarity to descriptions of flaps, we have previously suggested using the name of the main source

Fig. 21.3 Carl Manhot's vascular territories of the human integument. (A) Cutaneous vascular territories, ventral surface. (B) Cutaneous vascular territories, dorsal surface. (From Manhot C. *Die Hautarterien des menschlichen Körpers*. Leipzig: FCW Vogel, 1889.)

Fig. 21.4 Michel Salmon's vascular territories of the human integument, 1936. Summary of the cutaneous arterial territories of the ventral surface of the body. (From Salmon M. *Artères de la peau*. Paris: Masson, 1936.)

vessel to define the flap.^{30,31} Cormack and Lamberty³² published a book, *The Arterial Anatomy of Skin Flaps*, that contains a concise appraisal of the history, anatomy, and clinical aspects of skin flap surgery. The relationship of vessel size to vascular territory and axially of vessels in the fasciocutaneous system has also been described by Cormack and Lamberty.³³

The vertical rectus abdominis musculocutaneous flap was described by Michael Drever in 1977.³⁴ The transverse rectus abdominis muscle (TRAM) flap reported initially by Hartrampf *et al.*³⁵ demonstrated that the skin paddle survives based on the musculocutaneous perforators of the superior epigastric vessels. The pedicled and, later, the free TRAM flap became very popular for postmastectomy breast reconstruction. As the anatomy of the musculocutaneous perforators became better understood,^{36,37} surgeons harvested less of the rectus abdominis muscle in order to preserve function of the muscle. Investigators pushed the boundaries once again with the rediscovery of the perforator flap, whereby a large abdominal skin flap can be raised with preservation of the underlying rectus muscle and hence reduce the potential problems of an abdominal incisional hernia and abdominal wall weakness. This gradual change in flap design gave rise to the deep inferior epigastric artery perforator (DIEAP) flap based on perforators of the deep inferior epigastric vessels.³⁸ This evolution of autogenous reconstruction of the breast – from pedicled TRAM flap, to free TRAM flap, to muscle-sparing free TRAM flaps, to DIEAP flaps – reflects a greater awareness of the precise anatomy of the underlying musculocutaneous perforators and an attempt to reduce donor site morbidity and improve results. As knowledge of individual perforators to the skin improved, the spectrum of flap options increased dramatically.³⁹ There has been a virtual explosion in published surgical work regarding perforator flaps.

The recent enthusiasm for perforator flaps has heightened awareness of the vascular supply to tissues of the body.⁴⁰ Instead of 10–20 named arterial flaps in the body we now have a vast array of flap options based on any one of the over 400 arterial perforators of the body. This heightened awareness has led to greater understanding of the seemingly infinite possibilities for customized flap options.

flap,⁵⁹ profunda femoris artery perforator flap,⁶⁰ and the superior and inferior gluteal artery perforator flaps.⁶¹

The investigations initially involved an analysis of various regions of the body to define possible donor sites for free skin flap transfer.⁶² The studies subsequently focused on other tissues and included the anatomic basis for the transfer of bone,⁶³ nerve,⁶⁴ and certain muscles.^{21,65} Encouraged by the success of some of the resulting clinical procedures, the authors expanded the research to investigate composite units of tissue, supplied by a single vascular system. Units of skin and tendon,⁶⁶ muscle with nerve,⁶⁷ and skin, muscle, and bone^{68–70} were analyzed. It was from this work that the angiosome concept germinated. Various regions, including the anterior abdominal wall,^{21,36,65,71} the anterior thorax,^{72,73} the lower limb, and the upper limb, were studied. The results added strength to the angiosome concept of the blood supply and revealed the interconnections that exist at all levels between adjacent vascular territories, a relationship that is evident throughout the body.⁷⁴

In cadaver vascular research, various techniques can be used to identify and study the area of interest. In the past, the integument (skin and subcutaneous tissue) was removed, and the sites of emergence of the dominant cutaneous perforators (0.5 mm diameter or more) were identified on the surface of the deep fascia with lead beads. Currently, individual perforators are easily identified on CT angiography (CTA). Approximately 400 cutaneous perforators on average were identified per body.^{40,47} The three-dimensional branching pattern of main source vessels can be identified. Previous workers, including Salmon, had made topographic boundary incisions to remove areas of skin, particularly in the lines of the groins, axillae, neck, and limb joints (Fig. 21.5). These junctional regions are of great clinical importance, and for this reason the incisions were designed to retain their continuity wherever possible. In our current techniques, using CTA, the incisions utilized for dissection are not as crucial since the pathway and branches of individual vessels are clearly documented prior to dissection.

Fig. 21.5 appears online only.

In the original studies of the vascular supply of tissues of the body, the integument was radiographed, and a montage of the entire cutaneous circulation was constructed in “plan view” (Figs. 21.6, 21.7).⁴⁷ Although Manchot and Salmon described the origin and course of the cutaneous arteries, and Salmon⁹ made a separate study of the individual muscles, neither worker illustrated the course of the arteries between the deep tissues and the skin. Therefore, the skin and subcutaneous tissues were cut into parallel strips and placed on their side, and radiographs were taken to provide “elevation views” of the vessels in different regions of the body (Fig. 21.8). Current CTA techniques allow a far more detailed three-dimensional appraisal of the vascular anatomy of tissues (Fig. 21.9).

Fig. 21.6 appears online only.

All cutaneous perforators of diameter greater than 0.5 mm were traced to their underlying source arteries. The results were averaged from each cadaveric study and plotted on a diagram of the body (Fig. 21.10). Subsequently, investigations were expanded to map out the venous territories (venosomes) of the body along with the neurovascular territories of the skin and muscle.⁴⁸ These results have led to an overall picture of the vascular territories of the entire body. The remainder of

Fig. 21.7 Montage of the cutaneous arteries of the body. The skin has been incised along the ulnar border in the upper extremities, and the integument has been removed with the deep fascia on the left side and without it on the right. Note: (1) the direction, size, and density of the perforators, which are large on the torso and head and become progressively smaller and more numerous toward the periphery of the limbs; and (2) the reduced-caliber (choke) anastomotic arteries, which link the perforators into a continuous network. (From Taylor GI, Palmer JH. *The vascular territories [angiosomes] of the body: experimental study and clinical applications*. Br J Plast Surg. 1987;40:113.)

this section gives a brief overview of the arterial, venous, and nervous territories of the body.

Arterial territories

The arterial network of the body forms a continuous interlocking arcade of vessels throughout each tissue and throughout the body, linked by reduced caliber choke anastomotic vessels or true anastomoses. The course of the cutaneous perforators depends on the proximity of the source artery to the undersurface of the deep fascia. As Michel Salmon noted in 1936,⁸ arteries supply branches to each tissue that they pass, including the intermuscular septae, fascia, nerves, and tendons. Arteries generally fall into two groups, direct and indirect (Fig. 21.11). In our anatomical dissections, it is clear that there is great variability in the exact course and size of individual perforators; however, the main source vessels are relatively consistent. The direct cutaneous vessels pass

Fig. 21.5 Cadaver with body landmarks and incision lines marked. (From Taylor GI, Palmer JH. *The vascular territories [angiosomes] of the body: experimental study and clinical applications*. Br J Plast Surg. 1987;40:113.)

Fig. 21.6 Lateral view of one female subject (A) and anterior view of another (B). (A) The arm has been removed. Note the network of large vessels that sweep laterally from the ventral and dorsal midlines, ascend from the groins, descend from the shoulder girdle, and converge on the summits of the scalp and the breasts. This demonstrates the principle that vessels radiate from fixed concave zones and radiate to mobile convex areas. (B) A lower midline scar interrupts the vessels with compensatory opening of a large choke vessel above the umbilicus (arrow) to re-establish the flow across the midline. (From Taylor GI, Palmer JH. *The vascular territories [angiosomes] of the body: experimental study and clinical applications*. Br J Plast Surg. 1987;40:113.)

Fig. 21.8 Sectional strip radiographic studies of the breast (A), thigh (B), sole of the foot (C), and buttock (D). (D) includes the underlying gluteus maximus muscle. The schematic diagram illustrates the dominant horizontal axis of vessels that provides the primary supply to the skin in each case and its relationship to the deep fascia (arrow). (A) They predominate in the subdermal plexus. Note from left to right the internal thoracic perforator and lateral thoracic artery converging on the nipple in the radiograph of the loose skin region of the torso. (B) They are seen coursing on the surface of the deep fascia in this relatively fixed skin area. (C) The source artery itself is the dominant horizontal vessel supplying the skin, coursing beneath the deep fascia in this rigidly fixed skin region. (D) Small arrows define the deep fascia, and the large arrow indicates the large fasciocutaneous branch of the gluteal artery, which descends with the posterior cutaneous nerve of the thigh. (From Taylor GI, Palmer JH. *The vascular territories [angiosomes] of the body: experimental study and clinical applications*. Br J Plast Surg. 1987;40:113.)

between the deep tissues before piercing the outer layer of the deep fascia. They are usually the primary cutaneous vessels and their main destination is the skin. They tend to supply the skin with larger-diameter vessels which have a large vascular territory (e.g., circumflex scapular artery). The direct branches include direct cutaneous vessels (sometimes called axial vessels) and septocutaneous vessels. The indirect vessels can be considered the secondary cutaneous supply. They emerge from the deep fascia as terminal branches of arteries which supply the muscles and other deep tissues. The majority of indirect branches are musculocutaneous perforators which emerge to supply the skin. In fact, there is usually significant variability in the distribution of direct and indirect vessels and their vascular territory from individual to individual. There is a vast interconnected network of direct and indirect arteries which supply the skin. The vascular territories of individual perforators vary and tend to be reciprocal with adjacent arterial vascular territories according to the so-called

law of equilibrium, described by Salmon and supported by our work.

The direct cutaneous vessels arise from: (1) source arteries just beneath the deep fascia (e.g., the superficial inferior epigastric artery); (2) direct continuation of the source artery (e.g., the cutaneous branches of the external carotid artery); (3) deeply situated source artery or one of its branches to a muscle; they follow the intermuscular septa to the surface (e.g., septocutaneous branches of the lateral circumflex femoral artery). Indirect cutaneous vessels generally emerge from the main source artery as it courses on the undersurface

Dalhousie University, Halifax, Nova Scotia, Canada.*)

of a muscle and penetrate through the muscle; e.g., musculocutaneous perforators of the deep inferior epigastric arteries (DIEA). In the human body, there are approximately 400 perforators, about 40% of vessels are direct and 60% indirect perforators.

The direct cutaneous perforators pierce the deep fascia near where it is anchored to bone or the intermuscular and intramuscular septa (see Fig. 21.10). These lines and zones of fixation also correspond to the fixed skin areas of the body. From these points, the vessels flow toward the convexities of the body surface, branching within the integument. In general, the wider the distance between the cavities and the higher the summit, the longer the vessel (see Fig. 21.8). The size and density of the direct perforators also vary in different regions. For example, in the head, neck, torso, arm, and thigh, the vessels are larger, longer, and less numerous. In the forearm, leg, and dorsum of the hands and feet, the vessels tend to be smaller, shorter, and more numerous. In the palms of the hands and the soles of the feet, where the skin is fixed, there is a high density of smaller perforators. Hence, the primary supply of each cutaneous territory varies between source arteries. Each of these territories also has indirect perforators.

The course of the cutaneous perforators between the deep fascia and the skin also varies in different regions. Regardless of their site, however, they follow the connective tissue framework of the superficial fascia, interconnecting at all levels. They ramify on the undersurface of the subcutaneous fat adjacent to the deep fascia and then branch and course toward the subdermal plexus, working their way between the fat lobules. The smaller vessels tend to course vertically toward the skin, whereas the larger vessels branch in all directions in a stellate pattern or course in a particular axis, branching as they pass parallel to the skin surface.

In the scalp and limbs, where the skin is relatively fixed to the deep fascia, the larger vessels hug that surface. They course on the deep fascia for a considerable distance in the loose areolar layer that separates them from the subcutaneous fat (see Fig. 21.8). This is especially true when a perforator accompanies a cutaneous nerve.

In the loose skin areas of the body, the direct cutaneous vessels course for a variable distance parallel to the deep fascia. They are more intimately related to the undersurface of the subcutaneous fat, however, being plastered to it by a thin fascial sheet that separates them on their deep surface

from a plexus of smaller vessels. This plexus lies in loose areolar tissue on the surface of the deep fascia. It is formed by branches that arise from the direct perforators as they pierce the deep fascia and the connections these branches make with smaller indirect perforators. The large direct perforators then pierce the subcutaneous layer. They ascend within the superficial fascia (subcutaneous fat) to reach the rich subdermal plexus, where they travel for considerable distances (see Fig. 21.8).

Within the deep tissue, whether muscle, tendon, nerve, or bone, a pattern similar to that in the integument exists, with a three-dimensional network of vessels interlinking between vascular territories, the perimeters of which are linked by choke arteries. Within the muscles, these choke vessels often exhibit a characteristic corkscrew appearance on angiography.

Venous drainage

The cutaneous veins also form a three-dimensional plexus of interconnecting channels throughout the body (Fig. 21.12). There are valved segments in which valves direct flow in a particular direction, and there are avalvular segments where no valves are present. The avalvular or oscillating veins allow bidirectional flow between adjacent venous territories. They connect veins whose valves may be oriented in opposite directions, thus providing for the equilibration of flow and pressure. Indeed, there are many veins whose valves direct flow initially in a distal direction, away from the heart, before joining veins whose flow is proximal. An example of this is the superficial inferior epigastric vein that drains the lower abdominal wall integument toward the groin. In some regions, valved channels direct flow radially away from a plexus of avalvular veins, for example, in the venous drainage of the nipple–areola complex. In other areas, valved channels direct flow toward a central focus, as seen in the stellate branches of the cutaneous perforating veins of the limbs.

In general, venous anatomy parallels arterial anatomy (Fig. 21.13). From dermal and subdermal venous plexuses, the veins collect either into horizontal large-caliber veins, where they often relate to cutaneous nerves and a longitudinal system of chain-linked arteries, or alternatively in centrifugal or stellate fashion into a common channel that passes vertically down in company with the cutaneous arteries to pierce the deep fascia. Thereafter, the veins travel with the direct and indirect cutaneous arteries, draining ultimately into the venae comitantes of the source arteries in the deep tissue.

In general, the origin, course, and distribution of the deep veins (vena comitantes) are a mirror image of the deep source arteries, but they are larger and more plentiful. Although the anatomy of the veins is subject to considerable variation between sides in the same individual as well as between other individuals, the pattern of venous arcades is evident throughout. These arcades generally become smaller and more numerous as the periphery of the region or the tissue is reached. The superficial veins, however, are independent of the deep arteries (e.g., greater saphenous vein, cephalic vein) and may have a different area of drainage. For example, in the forearm there are paired vena comitantes to the radial and ulnar arteries but a separate system of large-caliber subcutaneous veins, including cephalic, basilic, and antebraclial veins.

The site and density of the valves within the deep venous network are variable. The deep veins follow the bony skeleton

Fig. 21.12 The venous network of the integument of a female subject. This is a montage of venograms from an injection study. (From Taylor GI, Caddy CM, Watterson PA, et al. *The venous territories [venosomes] of the human body: experimental study and clinical implications*. *Plast Reconstr Surg*. 1990;86:185.)

of the body or the intermuscular septa with their associated arteries. In some regions, these veins are single; in others, they are duplicated as *venae comitantes*. In the limbs, the veins commence distally in the hands and feet as single channels linked by venous arcades. These arcades become progressively larger as they approach the wrist and ankle. The veins are duplicated in the forearm and leg, and each pair of veins

is linked by a rich stepladder of venous channels that are usually free of valves. These *venae comitantes* then reunite to form single channels. In the lower limb, this occurs in the popliteal fossa, but in the upper limb, the union is most commonly in the proximal arm or even as high as the axilla.

In the torso, the pattern of arcades is conspicuous (see Fig. 21.13); the parent veins are oriented as longitudinal and transverse arcades that match the pattern of the source artery. Distinct territories are evident. Where choke arteries define the arterial territories, they are matched by oscillating veins in the venous network. The existence of *venae comitantes* is variable.

Within the muscle, the intramuscular venous network mirrors that of the arterial side. Where arterial territories are linked by choke arteries or true anastomotic arteries without changing caliber, the venous territories of the muscles, which drain in opposite directions, are linked by avalvular oscillating veins. Broadly, the muscles can be classified into three types on the basis of their venous architecture. Type I muscles have a single venous territory that drains in one direction. Type II muscles have two territories that drain from the oscillating vein in opposite directions. Type III muscles consist of three or more venous territories that drain in multiple directions (Fig. 21.14).

The extramuscular veins are of two types. The first group consists of the efferent veins. They contain valves and drain the muscles to their parent veins. The other group consists of the afferent veins. They are derived from the overlying integument as musculocutaneous perforators or from adjacent muscles (see Fig. 21.14).

Neurovascular territories

In our anatomical studies of neurovascular territories, fresh human cadavers were injected with a radiopaque lead oxide mixture, and the nerves were dissected and labeled with fine computer wire.⁴⁹ The nerves and vessels were then segregated by subtraction angiography.

The most obvious feature seen throughout the skin and muscle is the linear arrangement of the nerves and their branches, compared with the looping arcades of the interconnecting vessel network, with the nerves taking the shortest route between two points. In general, the orientation of cutaneous nerves is longitudinal in the limbs, transverse or oblique in the torso, and radiating from loci in the head and neck. Of particular note is that the cutaneous nerves, like the arteries, pierce the deep fascia at fixed skin sites.

Each cutaneous nerve is accompanied by an artery, but the relationship is variable. Some of the arrangements seen in the integument are shown in Fig. 21.15. In each case, either a long artery or a chain-linked system of arteries “hitchhikes” with the nerve.

When the cutaneous nerve and artery appear at the deep fascia together, their relationship is often established early (e.g., the lateral intercostal neurovascular perforators on the torso or the saphenous system in the lower limb). However, the nerve sometimes pierces the deep fascia at a point remote from the emergence of its associated artery (e.g., the lateral cutaneous nerve of the thigh and the superficial circumflex iliac artery below the inguinal ligament; Fig. 21.16). Alternatively, the nerve leaves one vascular system with which it is traveling in parallel to cross the path of another

Fig. 21.13 (A) Arterial and (B) venous studies of the anterior torso. Note the “corkscrew” choke arteries that link adjacent territories in the arterial study and the mixture that has extruded from the deep inferior epigastric veins as a result of the resistance of the valves. Radiographic lead beads identify the origin of the cutaneous perforators from their source vessels in the arterial study. (From Taylor GI, Caddy CM, Watterson PA, et al. *The venous territories [venosomes] of the human body: experimental study and clinical implications*. Plast Reconstr Surg. 1990;86:185.)

Fig. 21.14 Illustrations and radiographs of venous injection studies of the supraspinatus (A), gracilis (B), and sartorius (C) muscles. Note the oscillating veins that separate them into type I, II, and III muscles and the efferent veins entering the supraspinatus and gracilis muscles (dashed arrows). (From Taylor GI, Caddy CM, Watterson PA, et al. *The venous territories [venosomes] of the human body: experimental study and clinical implications*. Plast Reconstr Surg. 1990;86:185.)

Fig. 21.15 The neurovascular patterns found in the integument. **(A)** A long artery connected to its neighbor by a true anastomosis courses with the nerve. **(B)** A chain-linked system of arteries hitchhikes with the nerve. **(C)** The nerve and artery pierce the deep fascia at separate sites. Branches of the vessel peel off to accompany the nerve as it crosses the main arterial trunk. **(D)** The nerve at first courses parallel to an artery and then approaches the neighboring artery from its periphery to descend along its branches toward the main trunk. **(E)** The nerve crosses the primary and secondary arcades of the artery before coursing parallel to the vascular network. (From Taylor GI, Gianoutsos MP, Morris SF. *The neurovascular territories of the skin and muscles: anatomic study and clinical implications*. Plast Reconstr Surg. 1994;94:1.)

(e.g., the lateral intercostal nerve, which courses initially with its artery and then leaves it to meet the superficial inferior epigastric vessel). In many of these cases, secondary or tertiary branches of the artery often peel off to accompany the nerve (see Fig. 21.16). Sunderland noted that each peripheral nerve is abundantly vascularized by a “vascular net” of a series of nutrient arteries entering the nerve at different levels.⁷⁵

Fig. 21.16 appears online only.

The vascular architecture of the intramuscular veins and arteries is almost identical for each muscle. Therefore, to simplify the description of the nervous supply to the muscles, only the arterial relations of the nerves are discussed and illustrated. The intramuscular branches of the nerves were dissected to, but not within, the individual muscle bundles. The following observations were made:

1. The nerves follow the connective tissue framework. Dissection showed the motor nerves coursing in the connective tissue sheath from its origin at the nerve trunk to the neurovascular hilum of the muscle. Thereafter, the nerve and its branches follow the

intramuscular connective tissue to reach the muscle bundles.

2. The nerves are economical. As in the integument, the direct course of the motor nerves is in stark contrast to the wandering pattern of the vessels. The nerves take the shortest extramuscular and intramuscular routes compatible with the function of each muscle.
3. Neurovascular relations vary with the muscle, the extramuscular course, and the intramuscular branching of the nerves and the vessels. Some muscles have a single nerve supply; others receive multiple motor branches. All receive multiple arterial pedicles. However, despite the variables, certain observations can be made:

- Each motor nerve is accompanied by a vascular pedicle, but the reverse does not apply.
- The motor nerve is usually accompanied by the dominant vascular pedicle. There are exceptions to this, however. For example, the nerve supply to sternocleidomastoid is usually accompanied by a minor vascular pedicle.
- The nerve may enter the muscle before branching.
- Once within the muscle, the nerve divides early, and its branches sweep rapidly into position, parallel to the muscle fibers. The vessels, however, branch and form primary and secondary arcades, often crossing the muscle bundles and nerves before tertiary and quaternary branches are provided to the muscle fibers.

Ultimately, the terminal branches of the vessels and nerves come into close contact and course together in the connective tissue framework parallel to the muscle bundles.

Neurovascular anatomy of muscles of the body

Several methods have been used to classify muscles on the basis of morphology, function, blood supply, or nerve supply (Table 21.1). We have classified muscles of the body according to their most common pattern of innervation (Fig. 21.17). The pattern of neurovascular anatomy of the muscles influences the way a whole muscle or segment of muscle can be harvested as a functioning muscle microvascular transfer. It is possible to subdivide certain muscles, based on the neurovascular anatomy, into separate neurovascular units if each segment has an individual vascular pedicle. Clinically, serratus anterior, latissimus dorsi, gracilis, and rectus femoris are often used in this way, taking a portion of the muscle with their motor nerve and blood supply.^{55,56}

- Type I. The muscle is supplied by a single motor nerve that divides after entering the muscle (Fig. 21.18). Multiple vascular pedicles supply each muscle and form a continuous network throughout the tissue. It is possible in each case to remove a vascularized segment of muscle with its nerve supply and yet leave viable muscle *in situ*.
- Type II. A single motor nerve supplies each of the muscles in this group, but the nerve divides before entering the muscle. Muscles in this group include the deltoid (see Fig. 21.18), gluteus maximus, trapezius, vastus lateralis, serratus anterior, and flexor carpi ulnaris.

Fig. 21.16 Arterial injection of the right upper limb and torso. **(A)** Note the chain-linked systems of arteries (arrows) that course with the cutaneous nerves in the upper limb. **(B)** On the torso, the nerves are marked on the arterial study. They course with the cutaneous arteries, cross them at angles and collect arterial branches, or approach the arteries from opposite directions (arrows). (From Taylor GI, Palmer JH. *The vascular territories [angiosomes] of the body: experimental study and clinical applications*. Br J Plast Surg. 1987;40:113; and Taylor GI, Gianoutsos MP, Morris SF. *The neurovascular territories of the skin and muscles: anatomic study and clinical implications*. Plast Reconstr Surg. 1994;94:1.)

Table 21.1 Classification of muscles based on their nerve supply

Type I	Type II	Type III	Type IV
Latissimus dorsi	Deltoid	Gastrocnemius	Rectus abdominis
Extensor indicis	Gluteus maximus	Sartorius	Levator scapulae
Extensor pollicis longus	Trapezius	Tibialis anterior	Internal oblique
Abductor pollicis longus	Vastus lateralis	Flexor digitorum superficialis	Digastric
Palmaris longus	Serratus anterior	Subscapularis	Erector spinae
Teres minor	Flexor carpi ulnaris	Teres major	
Extensor hallucis longus	Biceps brachii	Triceps	
Plantaris	Brachialis	Extensor carpi ulnaris	
Popliteus	Flexor pollicis longus	Extensor digitorum longus	
	Flexor hallucis longus	Gluteus medius	
	Pectineus	Gluteus minimus	
	Adductor longus	Vastus medialis	
	Adductor brevis	Vastus intermedius	
		Peroneus longus	
		Soleus	
		Tibialis posterior	

- Type III. Multiple motor nerve branches derive from the same nerve trunk (see Fig. 21.18). Once again, it is possible to subdivide each muscle into separate functional units because of the multiple vascular pedicles as well as the several nerve branches. Gastrocnemius is often split in this way, taking one head for reconstruction, leaving behind the other functional unit with its neurovascular supply attached.
- Type IV. Multiple motor nerves are derived from different nerve trunks (see Fig. 21.18). It is apparent that each muscle can be subdivided anatomically into several functional units because of the multiple, often segmental neurovascular pedicles. Indeed, several of these muscles are formed developmentally by the fusion of adjacent somites (e.g., rectus abdominis and internal oblique).

The angiosome concept

Following a review of the works by Manchot and Salmon, along with the results of our total body studies of blood supply to the skin and the underlying deep tissues, it has been possible to divide the body anatomically into three-dimensional vascular territories named angiosomes. Each of these three-dimensional angiosomes is supplied by a source (segmental or distributing) artery and its accompanying vein or veins (Figs. 21.22–21.24). Each angiosome can be subdivided into

Fig. 21.17 Classification of muscle on the basis of nerve supply. (From Taylor GI, Gianoutsos MP, Morris SF. *The neurovascular territories of the skin and muscles: anatomic study and clinical implications*. Plast Reconstr Surg. 1994;94:1.)

Comparative anatomy

In the course of parallel investigations to describe animal models for vascular studies, it was noted that there are close similarities in vascular anatomy between animal species. However, there are also important differences of which investigators should be aware. The purpose of this section is to provide a more complete picture of the vascular territories. As we shall see, the angiosome concept can be applied equally to other members of the animal kingdom as well as to humans.⁵³

In plastic surgical research, selection of various animals for the study of flap physiology is based on cost, convenience, availability, and/or ethical considerations rather than on a profound knowledge of their vasculature. The pig, for example, is a fixed-skin animal, and because human integument is also fixed in many areas, it has been assumed that this animal is therefore most ideally suited for experiments on skin flaps. It is important to understand the vascular basis of the experimental animal model since results may not be generalizable to humans.

Study of these animals also leads us to gain further insight into the development and arrangement of the vascular system. It may aid in identification of the ideal animal for other experiments, such as investigation of the delay phenomenon, use of tissue expansion, programming of vessels, and prefabrication of flaps – whether they are skin, other tissues, or combinations of tissues.

When the radiographs of four animals are reviewed (Fig. 21.19), it is obvious there is a marked dissimilarity in the vasculature of the integument between them and that of the

human (see Fig. 21.7). Surprisingly, however, this is in marked contrast to the dramatic similarity of the radiographs of deep tissue of the mammalian torsos (Fig. 21.20).

The pattern of the cutaneous vasculature of the integument ranges from the fixed skin of the pig (supplied by a large number of small vessels over most of the hemitorso) to the mobile skin of the rabbit, in which four large vessels supply the majority of this area. The duck, not surprisingly, shows considerable diversity in the vasculature of its integument. Nevertheless, basic patterns are evident, having been modified by the growth and functional demands of the species.

The similarity in vasculature of the deep tissue is not confined to the anterior torso. Certain muscles between species have a remarkably similar vascularity, as can be seen in Fig. 21.21.

It appears that the vascular blueprint of the deep tissues of the torso of mammals remains relatively constant. It is simply enlarged from the fetus to the adult and from small to large mammals. The reason for this may be that the functional requirements of the torso are the same in each mammal, that is, respiration, protection of the viscera, and aid in removal of the contents. Beyond the deep tissues of the torso, it appears that the vasculature of the overlying integument, the head and the neck, and the limbs has been modified to meet the functional demands of each species, as Hunter⁷⁶ predicted more than 200 years ago.

Similarities are also seen in comparing the torso studies of mammals with those of other species, for example, the bird. In each case, vascular arcades arise from three basic sites: cranially from the subclavian and axillary vessels (aortic arch), laterally

Fig. 21.19 (A) Arteriogram of the skin of the pig. Note numerous small perforators on lateral torso, a superficial vein that has filled in the study (arrow), the larger segmental vessels near the ventral and dorsal midline, and the large perforator of the deep circumflex iliac artery near the hip. (B) Angiogram of the dog. Note the large perforator of the deep circumflex iliac artery and the thoracodorsal artery (arrows) near the hip and shoulder, respectively. (C) Arteriogram of the rabbit. Note the very large perforators of the deep circumflex iliac artery and thoracodorsal arteries dorsally and the superficial inferior epigastric artery and lateral thoracic arteries ventrally. Note also the large vessels supplying the ear. (D) Arteriogram of the duck. Note the discrete territories bounded by choke arteries and the long, stretched-out perforator of the transverse cervical artery in the mobile skin area of the neck (arrow). (From Taylor GI, Minabe T. *The angiosomes of the mammals and other vertebrates*. Plast Reconstr Surg. 1992;89:181.)

Fig. 21.20 Injection studies of the anterior torso with the integument removed and umbilicus located (large dot). The studies of the human and dog (A and C) are almost identical, with the deep inferior epigastric artery larger than the deep superior epigastric artery. In the pig and rabbit (B and D), the reverse applies. (From Taylor GI, Minabe T. *The angiosomes of the mammals and other vertebrates*. Plast Reconstr Surg. 1992;89:181.)

from the aorta (descending part), and caudally from the iliac and femoral vessels (terminal aorta). These three arcades form the basic vascular loops in the body that are common throughout the animal kingdom, including the human.

An underlying theme of the vascular architecture is that of vascular loops and arcades. Comparison of the vascular

architecture in the human with that of other animals and other species reveals a similar arrangement. In loose-skinned animals, the arcades in the integument are stretched over long distances (see Fig. 21.18). In the wings of insects and in the leaves of plants, the “veins” assume a pattern of interconnecting arcades similar to those of the intestinal mesentery.

Fig. 21.21 Comparative study of the rectus abdominis muscle from the various mammals studied. There is a striking similarity between the studies. However, in all animals except the pig, the muscle extends on to the thorax more cranially than in the human, and this region of the rectus receives additional branches from the internal thoracic artery. The reciprocal size relationship of the deep superior epigastric artery and deep inferior epigastric artery between species is a good example of the law of equilibrium. (From Taylor GI, Minabe T. *The angiosomes of the mammals and other vertebrates*. Plast Reconstr Surg. 1992;89:181.)

Fig. 21.18 Schematic diagram (left) of (A) type I (latissimus dorsi), (B) type II (deltoid), (C) type III (gastrocnemius), and (D) type IV (rectus abdominis) muscles to match radiograph (right) of each muscle. Nerves and vessels are seen together in the radiographs. The nerves are straight, whereas the vessels are spiral. The nerves, labeled with computer wire, appear black and the vessels pale and "ghost-like" in this subtraction study. (From Taylor GI, Gianoutsos MP, Morris SF. *The neurovascular territories of the skin and muscles: anatomic study and clinical implications*. Plast Reconstr Surg. 1994;94:1.)

Fig. 21.22 The technique by which the angiosomes were defined. **(A)** The cutaneous perforators with their choke connections are depicted on the left. The origin of the perforators from their underlying source arteries and their muscle branches is shown on the right. **(B)** The vascular territories of each source artery are illustrated in the integument (left) and deep tissues (right) by lines drawn through the choke connecting vessels. Note that the territories correspond in these two layers and how they appear as sectors in the limbs. (From Taylor GI, Palmer JH. *The vascular territories [angiosomes] of the body: experimental study and clinical applications*. Br J Plast Surg. 1987;40:113.)

matching arteriosomes (arterial territories) and venosomes (venous territories) or into further subunits based on individual perforators to the skin. Forty of these territories were initially described,⁷³ but subsequent investigation has led to many of these territories being subdivided further into smaller composite units and revealed some that do not reach the skin surface. In a later study, 61 vascular territories were identified.⁴⁰ Recent work has illustrated no fewer than 13 angiosomes of the head and neck, originally mapped as eight supplied by branches of the external carotid, internal carotid, and subclavian arteries.⁵² The angiosome concept indicates that the three-dimensional block of tissue is supplied by a major source artery and its accompanying vein(s), but it is important to note that the angiosome itself may be divisible depending on the branching pattern of the source vessel.

These composite blocks of skin, bone, muscle, and other soft tissues fit together like the pieces of a jigsaw puzzle, to make up the vascular supply of the body. In some of the angiosomes, there is a large overlying cutaneous area and a relatively small deep tissue region; in others, the reverse pattern exists. Each angiosome is linked to its neighbor at every tissue level, either by a true (simple) anastomotic arterial connection without change in caliber of the vessel or by a reduced-caliber choke anastomosis. A similar pattern with avalvular (bidirectional or oscillating) veins on the venous side links adjacent venosomes (see Fig. 21.24).

The angiosome concept has several important clinical implications:

1. Each angiosome defines the safe anatomic boundary of tissue in each layer that can be transferred separately or combined on the underlying source vessels as a composite flap (e.g., skin and muscle, muscle and bone, etc). Also, the anatomic territory of each tissue in the adjacent angiosome can usually be captured with safety when it is included in the flap design based on one of the source vessels.
2. Because the junctional zone between adjacent angiosomes usually occurs within muscles of the deep tissue, rather than between them, these muscles provide an important anastomotic detour (bypass shunt) if the main source artery or vein is obstructed.
3. Because most muscles span two or more angiosomes and are supplied from each territory, one is able to capture the skin island from one angiosome by muscle supplied in the adjacent territory. As we shall see later, this fact provides the basis for the design of many musculocutaneous flaps.

The anatomical and clinical territory of a cutaneous perforator

The angiosome concept provides a framework to understand the vascular anatomy of the human body. Plastic surgeons tend to focus on the vascular anatomy of skin but the angiosome concept applies equally to all tissues. The main vascular trunks which supply each angiosome are relatively consistent

Fig. 21.23 The angiosomes of the source arteries of the body shaded to correspond to Fig. 21.10. The angiosomes are: (1) thyroid; (2) facial; (3) buccal (internal maxillary); (4) ophthalmic; (5) superficial temporal; (6) occipital; (7) deep cervical; (8) transverse cervical; (9) acromiothoracic; (10) suprascapular; (11) posterior circumflex humeral; (12) circumflex scapular; (13) profunda brachii; (14) brachial; (15) ulnar; (16) radial; (17) posterior intercostals; (18) lumbar; (19) superior gluteal; (20) inferior gluteal; (21) profunda femoris; (22) popliteal; (22a) descending genicular (saphenous); (23) sural; (24) peroneal; (25) lateral plantar; (26) anterior tibial; (27) lateral femoral circumflex; (28) adductor (profunda); (29) medial plantar; (30) posterior tibial; (31) superficial femoral; (32) common femoral; (33) deep circumflex iliac; (34) deep inferior epigastric; (35) internal thoracic; (36) lateral thoracic; (37) thoracodorsal; (38) posterior interosseous; (39) anterior interosseous; and (40) internal pudendal.

in size and position, however the individual cutaneous perforators are highly variable in size and position. Each individual cutaneous perforator territory fits together with its neighboring territories like a giant jigsaw puzzle (Fig. 21.25). The arterial connection between adjacent cutaneous perforators may be through reduced caliber choke anastomotic vessels or through vessels which are not reduced in caliber (true anastomoses).⁷⁷ True anastomoses occur variably throughout the body, most commonly along cutaneous nerves or in areas where the skin is mobile.⁷⁸

The importance of true anastomoses relates to the clinical territory of an individual cutaneous perforator. Generally, it has been found in experimental work on a series of animals including pig, dog, guinea pig and rabbit that the limit of viability of a skin flap is related to the anatomy of the pedicle of the flap and the surrounding perforator angiosomes.⁷⁸ Based on the flap perforator, it is possible to reliably capture an adjacent cutaneous territory in any direction. In about 80% of the animal studies, the limit of flap survival was at the junction between second and third territory.

However, if there are true anastomoses between vascular territories, the third territory potentially could be captured based on an individual perforator. This would be analogous to a delay procedure (see Fig. 21.53) in which the choke anastomotic vessels dilate between vascular territories, increasing flap survival. Thus, it is the vascular anatomy of individual perforators and the vascular connections between perforators which govern the survival of flaps based on the perforator. A novel technique using dynamic thermography to preoperatively map cutaneous perforators and their interconnections has been reported which is non-invasive and non-irradiating and shows promise as a tool to predict flap survival.⁷⁹

Vascular territories of the body

The angiosome concept has led to the segregation of the body anatomically into three-dimensional vascular territories. Further work has led to the investigation and detailing of angiosomes in certain parts of the body. Some of these regions are highlighted to expand and to clarify the concept. The description of vascular territories is important to the design of flaps throughout the body.

Vascular territories of the forearm

The forearm is an important flap donor site due to the high incidence of hand and upper extremity injuries around the world.⁵⁰

Forearm skin

The cutaneous perforators arise directly from the source arteries or from their muscular branches, and then they follow the intermuscular septa distally. Proximally, perforators pierce the muscle bellies near where the muscles are fixed at their origins from bone or from the intermuscular septa. The perforators become more numerous but smaller distally, with the maximum number of small perforators being seen in the palm, where the skin is most rigidly fixed. The cutaneous perforators on both the anterior and posterior surfaces of the forearm emerge in rows along the course of the radial and ulnar arteries (Fig. 21.26).

Muscles

In general, muscles are supplied by vascular pedicles from each angiosome that they span. These can be divided into the anterior group and the posterior group.

The anterior group of forearm muscles can be further subdivided into the superficial and deep muscles. The superficial

muscles proximally receive branches from the brachial artery, the ulnar artery, or the ulnar recurrent artery. Distally, they receive branches from the radial artery or ulnar artery (Fig. 21.27).

The deep anterior muscles are supplied by the radial artery, the anterior interosseous artery, and the ulnar artery. Note in Fig. 21.27 that the junctional zone between angiosomes occurs primarily within the muscles and that most muscles span at least two angiosomes.

The posterior group again can be divided into superficial and deep muscles. The superficial muscles receive blood from the radial recurrent artery, which supplies the proximal and lateral halves of their muscle bellies. The distal and medial halves of these muscles receive their blood supply from the posterior interosseous and the interosseous recurrent arteries (Fig. 21.28). The deep muscles receive their blood supply from the radial recurrent artery, interosseous recurrent artery, posterior interosseous artery, and anterior interosseous artery.

When cross-sectional studies of the forearm are reviewed, it becomes clear that the angiosomes of each source artery span between the skin and the bone (Fig. 21.29). It is noteworthy that the proportional representation of each source artery varies between levels in the forearm. Although the angiosome of the anterior interosseous artery does not reach the skin in Fig. 21.29, it eventually surfaces in the distal forearm posteriorly or where the anterior interosseous artery provides a dominant median branch. In the latter case, it supplies the skin on the volar surface.

Forearm bones

The bones of the forearm also conform to the angiosome concept. The radius is supplied mainly by the radial artery by means of several large proximal branches and by very small distal septoperiosteal and musculoepiosteal branches. In the middle, it receives a nutrient branch from the anterior

Fig. 21.26 The cutaneous perforators of the forearm, color-coded to match the angiosomes. Large and small skin perforators are indicated by size of the colored markers. Compare with Fig. 21.22. (From Inoue Y, Taylor GI. *The angiosomes of the forearm: anatomic study and clinical applications*. Plast Reconstr Surg. 1996;98:195.)

interosseous artery. Distally, it also receives one or two small septoperiosteal branches from the anterior interosseous artery, and there is another blood supply from the posterior interosseous artery through the muscles that are attached to the bone.

The ulna is supplied predominantly by the ulnar artery, again through several large proximal and several small distal septoperiosteal branches. In the middle, it receives a nutrient branch from the posterior interosseous artery. Again, as with the radius, another blood supply enters through muscles

attached to the ulna, derived from branches of the anterior interosseous artery.

Clinical implications

Donor site morbidity

From these data, it is evident that the radius and ulna, and nearly every muscle in the forearm, receive a contribution from at least two source arteries. Also, there are intramuscular

Fig. 21.28 The vascular territories of the (A) superficial and (B) deep forearm extensor muscles, showing once again that the junctional zone lies primarily within the muscles. and extramuscular anastomoses around the elbow that are usually well developed, especially on the radial side. In addition to the connections within the muscles and skin, particularly well-developed anastomoses occur between vessels that travel on and within the deep and cutaneous nerves.

When the radial artery flap is harvested, the only muscles that lie solely within this angiosome are the brachioradialis, extensor carpi radialis longus, and extensor carpi radialis brevis, supplied by its radial recurrent branch. However, this branch has an excellent anastomosis with the profunda brachii artery. Experience confirms this observation and has shown that dissection of the radial forearm flap can proceed safely right up to the origin of the radial artery from the brachial artery, with either division of its recurrent branch or inclusion of this vessel with one or more of "the mobile mass" muscles.

A proximal dissection of the ulnar artery to its origin from the brachial artery, however, especially if the radial artery is smaller than usual, may lead to problems.

The flexor digitorum profundus and flexor carpi ulnaris are the only muscles supplied solely by the ulnar artery and its

anterior interosseous or recurrent interosseous branches (see Fig. 21.27). If these branches (or the common interosseous artery itself) are divided at their origin while a skin flap is harvested on the ulnar artery, survival of part or all of the flexor carpi ulnaris and flexor digitorum profundus will then rely on: (1) the anastomosis between the ulnar recurrent and the ulnar collateral vessels proximally, an anastomosis that may not be so well developed in some; (2) the anastomosis between branches of the radial artery and the anterior interosseous artery in the midforearm, especially within the flexor pollicis longus; or (3) the connections between the anterior interosseous and a reconstituted posterior interosseous artery in the distal forearm.

In contrast to the flexor digitorum profundus, the flexor digitorum superficialis is better protected because it has an additional contribution from the radial artery angiosome.

Free-flap donor sites

From the angiosome concept, and applying the anatomic knowledge in the previous sections, various tissues can be

Fig. 21.30 Vascular territories of the lower leg. The colored circles represent cutaneous perforators emerging from the deep fascia and depict relative size of the vessels. EDL, extensor digitorum longus; EHL, extensor hallucis longus; FDL, flexor digitorum longus; GAS, gastrocnemius; PB, peroneus brevis; PL, peroneus longus; PT, peroneus tertius; SO, soleus; TA, tibialis anterior. (From Taylor GI, Pan WR. *The angiosomes of the leg: anatomic study and clinical applications*. Plast Reconstr Surg. 1998;102:599.)

combined or raised separately on the forearm on the various source arteries and their accompanying veins. It has been shown clinically that the dimensions of a flap designed in one angiosome can be extended to include the anatomic territory of the adjacent angiosome in each tissue layer.

In the proximal forearm, the cutaneous blood supply from the radial and particularly the ulnar artery is often musculocutaneous. This is seen especially where muscles are fixed to bone or where they have a common fascial attachment, often before the muscles separate. In these circumstances (e.g., where the muscles arise from the common flexor or common extensor origin), the cutaneous vessels are derived usually from muscle branches and emerge from the muscles near these fixed attachments to bone or fascia.

Vascular territories of the lower leg

In the lower leg, the source arteries and their respective venae comitantes travel adjacent to, but not within, the rigid fascial envelopes of the leg.⁵¹ Here they are invested in loose connective tissue.

Lower leg skin

The cutaneous vessels in the lower leg, as in the forearm, arise from the source arteries or their muscle branches. They pierce the deep fascia in longitudinal rows in the vicinity of the intermuscular septa or beside tendons. They supply branches to each tissue they pass of the lower leg proximally, whether bone, muscle, nerve, fat, tendon, or fascia. There tends to be a line of cutaneous perforators over the anterior tibial, posterior tibial and peroneal vessels. These perforators provide the vascular basis of local perforator or “propeller” flaps for lower leg reconstruction. On the anterior surface proximally, these perforators usually emerge between the tibialis anterior and extensor digitorum longus, where they are derived from the anterior tibial artery, or between the flexor digitorum longus

and soleus muscles, where they arise from the posterior tibial artery (Fig. 21.30). Branches are seen also emerging between the tibia and tibialis anterior muscle and between the extensor digitorum longus and the peroneal muscles, these being derived from the anterior tibial artery. Distally, the vessels appear between the muscle bellies or between the tendons of the extensor digitorum longus, extensor hallucis longus, or peronei, obtaining their supply from the anterior tibial artery. Over the subcutaneous surface of the tibia where the skin is fixed, the deep fascia is continuous with the periosteum of the bone. In this area, branches of the anterior tibial and posterior tibial arteries anastomose freely over the surface of the periosteum.

In the posterior aspect of the leg, vessels pierce the deep fascia around the perimeter of muscles and tendons or from intramuscular septa. On occasion, they have a long intramuscular course and appear as terminal branches of a muscle artery; this is seen especially in the proximal perforators of the peroneal artery.

Lower leg muscles

In the lower leg, a picture similar to that in the forearm is seen, with muscles being supplied by vascular pedicles from each angiosome territory they span.

Anterior leg muscles

The muscles in this compartment are supplied exclusively by the anterior tibial artery (Fig. 21.31). A common vessel frequently passes through one muscle belly to supply the next as well as providing a cutaneous perforator.

This group of muscles is particularly vulnerable to ischemia because they are housed in a compartment with rigid walls across which vascular connections are sparse. This is particularly so medially, where the tibia is subcutaneous. Here the only connections between the anterior tibial and posterior tibial arteries are by means of the periosteum of the bone and

from within the cutaneous network. As can be seen from Table 21.2, all the muscles of this compartment lie in one territory.

Lateral leg muscles

The peroneus longus and peroneus brevis are supplied by the anterior tibial and peroneal arteries, thus forming an important, albeit tenuous, intramuscular connection between their two source arteries (see Fig. 21.31). These muscles are situated within a tight compartment bordered by the fibula, the anterior and posterior intermuscular septa, and the deep fascia. As with the anterior group muscles, the blood supply frequently passes through one peroneal muscle to reach the next, often hugging the fibula during its course.

Table 21.2 Leg muscle angiosomes	
One territory	Tibialis anterior Extensor digitorum longus Extensor hallucis longus Peroneus tertius
Two territories	Peroneus longus Peroneus brevis Flexor digitorum longus Flexor hallucis longus
Three territories	Gastrocnemius Soleus Popliteus Tibialis posterior

Fig. 21.31 Vascular territories of the lower leg. (A) Illustration of the anterior muscle group that lies totally within the anterior tibial angiosome (blue). This angiosome extends to include part of the peroneal muscles. (B) Illustration of the lateral muscles and their supply from the anterior tibial (blue) and peroneal (green) angiosomes. EDL, extensor digitorum longus; EHL, extensor hallucis longus; PB, peroneus brevis; PL, peroneus longus; PT, peroneus tertius; TA, tibialis anterior. (From Taylor GI, Pan WR. *The angiosomes of the leg: anatomic study and clinical applications*. Plast Reconstr Surg. 1998;102:599.)

Posterior leg muscles

The muscles here can be divided into a superficial group, comprising the gastrocnemius and soleus, and the deep group, comprising the flexor hallucis longus, flexor digitorum longus, tibialis posterior, and popliteus.

The superficial group lies superficial to and is supplied by branches of the popliteal, posterior tibial, and peroneal arteries. Of particular note, blood supply to the gastrocnemius arises proximally in the popliteal fossa from the popliteal artery by the medial and lateral sural arteries to each head of gastrocnemius with little overlap between muscle bellies. This is in marked contrast to soleus, where the blood supply is provided by a large number of short vessels from the posterior tibial, popliteal, and peroneal arteries, which anastomose freely within the muscle, thus forming a vital anastomotic link in the leg.

The deep muscles are supplied by the popliteal artery by means of its inferior genicular branches, the posterior tibial artery, the peroneal artery, and a contribution from the anterior tibial artery (Fig. 21.32).

The junctions between angiosomes, and hence the anastomoses between adjacent source arteries, occur usually within

tissues, especially the muscles, rather than between them (Fig. 21.33).

Leg skin vascular supply

Proximally in the leg, the cutaneous vessels often arise as terminal branches of the muscle arteries and travel to the surface nearby or adjacent to (not within) the intramuscular or intermuscular septa.

In the middle of the leg, the vessels tend to have a more direct course to the skin but again travel close to the septa, either adjacent to or within muscles. As they travel, they usually supply sizable branches to the bones, the muscles, and other tissues.

In the distal part of the leg, the cutaneous vessels have an even more direct course to the skin. However, they still provide branches to the tendons (especially the Achilles tendon), the bones, and the deep fat deposits during their course, a point to be remembered in dissecting the skin paddle of a fibula osteocutaneous flap.

The subcutaneous periosteal surface of the tibia contains anastomoses between the posterior and anterior tibial arteries. Most pretibial lacerations occur superficial to the periosteum

Fig. 21.32 Vascular territories of the lower leg. (A) The superficial muscle group with its supply from the arteries of the popliteal (purple), sural (orange), posterior tibial (yellow), and peroneal (green) angiosomes. and “shear off” the cutaneous arteries that emerge from this plexus, thus explaining the high incidence of traumatic skin flap necrosis.

Connective tissue framework

The source arteries and their venae comitantes travel adjacent to, but not within, the rigid fascial envelopes that make up the compartments of the leg. They travel in loose connective tissue, usually adjacent to one side of the fascial sheet. This is important surgically, for example, to approach these vessels

to dissect the pedicles of local or free flaps, to use the vessels as recipient sites for transplantation or replantation, or to avoid them in decompressing the leg of a patient with a compartment syndrome.

Compartment syndromes

It seems more than a coincidence that the compartment whose blood supply is anatomically most vulnerable to ischemia, the anterior tibial compartment, is the one most often affected by exercise to give the painful condition of “shin splints”. The

only vessel supplying the muscles of this compartment is the anterior tibial artery with its venous drainage paralleling the arterial supply.

Flap donor sites

Following McGraw and Dibbell's work on the musculocutaneous territories in the leg^{23,25} and Pontén's work,²⁸ which drew attention to the vessels hugging the deep fascia and septa in this region, a large number of flaps have been described based proximally and distally in the leg. In most cases, they have been designed after a review of the anatomy of the leg vessels. Wei *et al.*⁸⁰ have shown that a skin flap can be included with the fibula as a free flap. On review of the cutaneous perforators of the lateral aspect of the leg, it can be seen that the skin paddle should be designed distally in the leg to capture direct septocutaneous perforators from the peroneal artery. Dissection of the distal septocutaneous perforators of the peroneal artery tends to be the most straightforward since the proximal branches tend to have long intramuscular courses.

Vascular anastomoses around the knee

In the previous section on the forearm, emphasis was placed on the anastomoses around the elbow joint. Here, the mass of the brachioradialis, brachialis, and common flexor and extensor muscles plays an important role in bypassing potential obstruction of the brachial artery. The rich intramuscular anastomoses within these muscles between the radial and profunda brachii artery branch laterally, and between the ulnar and ulnar collateral vessels medially, supplementing the extramuscular anastomoses.

Around the knee, the story is very different. Few muscle bellies actually cross the knee joint; most are represented by tendons. The largest of these, the gastrocnemius, has a blood supply that arises in the popliteal fossa, not above it, and has a relatively poor connection with other vessels in the leg. The main anastomoses between the thigh and leg are extramuscular (except for popliteus), represented by the geniculate vessels. This helps explain the observation by Hunter and Salmon^{8,9} that ligation of the popliteal artery, proximal to the sural arteries, has a major effect on the blood supply to the distal leg.

In the popliteal fossa distally, the soleus muscle receives large branches from the popliteal artery, which link the branches of the posterior tibial and peroneal vessels within the muscle substance. This may explain why ligation of the popliteal artery distal to the takeoff of its branches to the soleus at the distal end of the popliteal fossa had little effect on perfusion of the leg, as observed by Salmon.^{8,9}

Vascular territories of the head and neck

The head and neck region is similar to the leg and forearm region in that the angiosomes are connected usually within the tissues, such as muscle, skin, specialized organs, or glands, rather than between the tissues.⁵² The muscles usually have vessels of two or more angiosomes supplying them and in general can be classified into three major groups on the basis of the similarity of their arterial supply (Tables 21.3–21.4). In some areas, the midline anastomoses are rich, especially in the integument of the scalp, forehead, and lips. In other

regions, such as the tongue and palate, the midline vascular connections – those of the vertebral, lingual, and ascending pharyngeal – are confined to the deep tissues without cutaneous representation.

Head and neck skin and superficial musculoaponeurotic system

The blood supply to the skin of the face, scalp, and neck follows the connective tissue framework. The main skin perforators pierce the deep fascia from fixed skin sites, especially around the base of the skull, around the orbits, around the nostrils, over the parotid gland, along the skin crease lines of the face, and beside the muscles in the neck. They then radiate into mobile skin areas and are intimately associated with the superficial musculoaponeurotic system (SMAS) layer in the face, the platysma in the neck, and the galea in the scalp (Fig. 21.34).

Vascular arcades occur widely in the scalp between the occipital, postauricular, and superficial temporal branches of

the external carotid system and the supraorbital, supratrochlear, and dorsal nasal branches of the internal carotid system. The major veins and arteries in the head and neck often run a different course and may be at a distance from each other.

In the neck, the blood supply is more sparse, with the main perforators emerging from their source arteries where the skin is attached (at the anterior border of the trapezius; along the anterior and posterior borders of the sternocleidomastoid; along the hyoid bone superiorly and the clavicle and sternum inferiorly). They form a rich plexus within the platysma muscle anteriorly (the counterpart to the SMAS in the neck) en route to the skin. The external ear is supplied by two angiosomes, the superficial temporal and the posterior auricular (Fig. 21.35).

The external nose has an abundant blood supply from the ophthalmic branch of the internal carotid and the facial branch of the external carotid artery. Classically, the external nasal branch of each ophthalmic artery runs down the dorsum of the nose to anastomose freely with the lateral nasal branch of the facial artery on each side as well as its superior labial branches. In summary, therefore, the external nose, like the external ear, has two angiosomes supplying it on each side

Fig. 21.34 Fresh cadaver lead oxide arterial study of the lateral (A) and anterior (B) view of the composite skin and superficial musculoaponeurotic system (SMAS) unit in the head and neck. The occipital (a), superficial temporal (b), and ophthalmic (c) arteries have been labeled. Note that the facial vein (v) runs a more direct course and at some distance to its arterial counterpart, the facial artery (d). (C) The skin layer alone reveals a vast arterial “blush” zone of the skin and SMAS shown in sagittal view. Note: (1) the rich arterial anastomotic “waves” formed between the branches of the occipital, superficial temporal, and ophthalmic arteries in the scalp; (2) the cluster of small vessels supplying the fixed skin area over the parotid gland and masseter muscle compared with the large branches of the facial artery that supply the mobile anterior face; and (3) the relative paucity of large vessels in the neck except in the anterior triangle. The SMAS layer is seen only in (D) with the muscles of facial expression outlined. They are: (1) frontalis; (2) procerus; (3) corrugator; (4) orbicularis oculi; (5) levator labii superioris alaeque nasi; (6) nasalis; (7) levator labii superioris; (8) zygomaticus minor; (9) zygomaticus major; (10) orbicularis oris; (11) depressor anguli oris; (12) depressor labii inferioris; (13) mentalis; and (14) platysma. (From Houseman ND, Taylor GI, Pan WR. *The angiosomes of the head and neck: anatomic study and clinical applications*. Plast Reconstr Surg. 2000;105:2287.)

Fig. 21.35 (A) Lead oxide arterial study of the blood supply of the ear and adjacent tissues. Note the arcades formed between the superficial temporal and posterior auricular arteries, highlighted with arrows. (B) Schematic picture shows the branches of the superficial temporal (dark) and posterior auricular (light) supply to the front and back of the ear, respectively. Note also the true and choke anastomoses between these two arteries in the scalp. (C, D) Close-up examination of the arterial anatomy of the external nose. Note the arcades that occur around the alar dome between the columella branch of the superior labial artery and the facial artery. The facial vein has also been partially filled with lead oxide and highlighted by the arrows. (From Houseman ND, Taylor GI, Pan WR. *The angiosomes of the head and neck: anatomic study and clinical applications*. Plast Reconstr Surg. 2000;105:2287.)

and provides a major connection between the internal and external carotid systems (Fig. 21.36; see Fig. 21.34).

The majority of the veins in the head and neck region are avalvular, and most of the valved veins have ostial valves sited at the entry of these bidirectional or oscillating veins into the large collecting directional veins.

Head and neck muscles

The muscles of the head and neck may be grouped according to the number of angiosomes they span and from which they receive a vascular supply (see Table 21.3). These muscles are subgrouped into regions. Together they form an important vascular connection through their intramuscular anastomoses, between branches of the internal carotid, external carotid, and subclavian vessels.

Muscles of facial expression

These muscles lie within the mobile panniculus of the scalp, face, and neck and the aponeurosis of the SMAS. They are intimately related to, are supplied by, and contain within themselves the major branches and cutaneous divisions of the occipital, superficial temporal, ophthalmic, facial, superior thyroid, and inferior thyroid arteries (see Figs. 21.34, 21.36). This whole muscle aponeurotic layer tethered at various points around the skull thus forms a rich continuous anastomotic layer extending from the occiput across the top of the head and face to the root of the neck. Because of the mobility, either the scalp or face, or a combination, can be involved in degloving and scalping injuries. However, because of the rich anastomosis between arteries both longitudinally and transversely across the midline, combined with the poverty of venous valves within their network, successful replantation

of the part without the need for large numbers of vascular anastomoses has been performed.⁸¹

The platysma muscle forms a vascular link between the external carotid and subclavian arteries through its branches of the superior thyroid or submental branch of the facial artery above and the transverse cervical and inferior thyroid

Fig. 21.36 Angiosomes of the muscles of facial expression and mastication in the face. (From Houseman ND, Taylor GI, Pan WR. *The angiosomes of the head and neck: anatomic study and clinical applications*. Plast Reconstr Surg. 2000;105:2287.)

arteries below. As a result, the muscle can be raised on either the superior or inferior pedicle.

The orbicularis oris muscle provides a vascular link between the left and right sides of the face through the facial artery and its superior and inferior labial artery branches. The robustness of this blood supply has been used clinically for more than 100 years in the Abbé flap^{1,82} lip reconstruction.

Ocular muscles

The six ocular muscles all lie within the territory of the ophthalmic artery angiosome. They are therefore potentially vulnerable to ischemia. However, peripherally they are protected by rich anastomoses formed between branches of the ophthalmic artery with (1) branches of the facial artery on the face and (2) branches of the internal maxillary artery in the temporal fossa and the nasal and cranial cavities.

Muscles of mastication

As a group, these muscles cross three angiosome territories, forming a link between the superficial temporal, internal

maxillary, and facial arteries through intramuscular connections (see Fig. 21.36). Buccinator, temporalis, and masseter are supplied by branches from two angiosomes and therefore can be raised on either vascular pedicle.

Posterior neck muscles

As a group, these muscles span and are supplied by up to six angiosome territories. There is thus a staircase of intramuscular vascular anastomoses, especially within the trapezius muscle; between the intercostal branches of the aorta; the suprascapular, transverse cervical, deep cervical, and vertebral branches of the subclavian artery; and the occipital branch of the external carotid artery (Fig. 21.37).

With respect to the trapezius, there is a significant variation in its vascular anatomy, depending on the origin of the dorsal scapular artery.⁸³ This may arise either as a branch of the transverse cervical artery or as a separate branch from the third part of the subclavian artery. As a result, the trapezius has either four or five territories (see Table 21.3).

Fig. 21.37 (A–D) The angiosomes of the head and neck colored and numbered to match Figs. 21.22 and 21.35. Angiosomes: (1) internal maxillary; (2) facial; (3) ophthalmic; (4) superficial temporal; (5) posterior auricular; (6) occipital; (7) transverse cervical; (8) deep cervical; (9) inferior thyroid; (10) superior thyroid. The sagittal section (B) shows the three angiosomes: (11) vertebral; (12) ascending pharyngeal; (13) lingual, that do not reach the skin surface. (From Houseman ND, Taylor GI, Pan WR. *The angiosomes of the head and neck: anatomic study and clinical applications*. Plast Reconstr Surg. 2000;105:2287.)

Lateral neck muscles

This group comprises the sternocleidomastoid muscle and the deep scalene muscles. Each spans two or more angiosomes and as a group through intramuscular links provides a pathway between the transverse cervical and inferior thyroid branches of the subclavian artery and the superior thyroid and the occipital branches of the external carotid artery (see Fig. 21.37).

Of note, the sternocleidomastoid has four angiosome territories, the principal two being from the occipital and the superior thyroid arteries. The lower two territories tend to be less dominant, coming from the inferior thyroid and the transverse cervical arteries. In head and neck reconstruction, the sternocleidomastoid muscle has been used for many years. It can be based either superiorly or inferiorly. However, when it is based superiorly, the skin flap located at the lower pole of the muscle has had a high incidence of loss of the skin paddle because of its poor blood supply. This relates to the number of vascular territories that blood from the superior pole must cross to reach the skin paddle. The musculocutaneous flap may be unreliable depending on the vascular supply to the flap and flap design.

Anterior neck muscles

Apart from the small thyrohyoid muscle, which occupies the angiosome territory of the superior thyroid artery, the remainder of these muscles occupy at least two territories (see Table 21.3). These muscles form a link between the occipital, lingual, and facial arteries (see Fig. 21.37).

Aerodigestive system

This system is supplied by no less than seven angiosome territories (see Table 21.4 and Fig. 21.37).

Internal nose

This area is supplied by three primary sources from the ophthalmic, maxillary, and facial artery angiosomes. There are a large number of anastomoses with the blood supply to the external nose (see Fig. 21.37).

Tongue and floor of mouth

The tongue can be divided into extrinsic and intrinsic musculature. The extrinsic muscles are either one-territory or two-territory muscles. Of note, the mylohyoid is supplied on its superficial surface by the submental branch of the facial artery on each side; anastomosis in the midline forms an arterial loop. On its deep surface, it is supplied by the lingual artery and the mylohyoid branch of the internal maxillary artery. The bulk of the intrinsic muscles are supplied by terminal branches of the lingual artery as the vessel enters the posterolateral portion of the tongue on each side. It also receives a small supply from the facial artery. Of note, however, the tongue has an obvious midline raphe, with a poor vascular crossover between the right and left sides (Fig. 21.38). This is of importance in resection of tongue tumors, raising the possibility of tongue tip necrosis on the ipsilateral side if the lingual artery is sacrificed.

Fig. 21.38 Radiograph of the tongue; note the almost avascular midline. (From Houseman ND, Taylor GI, Pan WR. *The angiosomes of the head and neck: anatomic study and clinical applications*. Plast Reconstr Surg. 2000;105:2287.)

Palate, pharynx, larynx, esophagus, and trachea

The region from the hard palate to the upper portion of the esophagus spans and is supplied by five angiosomes. These comprise the internal maxillary, facial, ascending pharyngeal, superior thyroid, and inferior thyroid arteries. There is a paucity of vessel crossover in the region of the hard palate, and this appears to extend into the pharynx in a fashion similar to the paucity in the midline of the tongue.

Glands

The salivary glands occupy one territory each. The parotid gland receives its supply from the transverse facial branch of the superficial temporal artery as well as a number of smaller branches from the superficial temporal artery.

The submandibular gland is supplied by the facial artery as it runs in the groove between the gland and the mandible. The sublingual gland receives its supply by sublingual branches of the lingual artery.

The thyroid gland spans two angiosome territories on each side, being supplied by the superior and inferior thyroid vessels. These vessels have a rich anastomotic network within each lobe of the thyroid and form an important connection between the subclavian and the external carotid systems on each side and between each side.

Fig. 21.24 The venosomes of the body. Compare with Fig. 21.22. (From Taylor GI, Caddy CM, Watterson PA, et al. *The venous territories (venosomes) of the human body: experimental study and clinical implications*. *Plast Reconstr Surg*. 1990;86:185.)

Anatomic concepts related to flap design

The following concepts provide an overview of the blood supply to the integument and to the deep tissues (Box 21.1). They are fundamental to the mapping of the vascular territories and to the planning of incisions and flaps. They help explain the anatomic variations that exist between the vessels of different regions of the body and allow better understanding of the various classifications of the cutaneous blood supply that have appeared in the literature. Finally, these anatomic concepts provide the basis for interpreting many physiologic and pathologic processes, including the delay phenomenon and the necrosis line of flaps.

Vessels follow the connective tissue framework of the body

This concept is fundamental to the design of flaps in general and to fasciocutaneous and septocutaneous flaps in particular. The connective tissue framework of the body is a continuous syncytium, like the walls of a honeycomb, calcified in some areas to form the bony skeleton, which houses, permeates, and supports the specialized tissues. The vessels follow this framework down to the microscopic level. Embryologically, vessels develop with connective tissue in the mesoderm and, through development, remain closely related. The clinical application of this is the septocutaneous or fasciocutaneous flap.

In general, if the connective tissue is rigid, such as intermuscular septa, periosteum, or deep fascia, the vessels travel beside or on it. If the connective tissue is loose, they travel within it. The vessels occasionally travel in a fibrous sheath or a bony canal, but this tunnel always contains loose areolar tissue, physiologically, to allow the veins to dilate and the arteries to pulsate.⁸⁴

The pattern is well illustrated if the arterial network is traced from the heart to the periphery. The major arteries are closely related to the bones of the axial skeleton (see Fig. 21.2). Their branches at first follow the intermuscular septa. In the deep tissues, they penetrate the muscles (usually on their

deep surface), tendons, bones, nerves, and deep fat deposits. As the vessels divide and subdivide within the specialized tissues, their branches again follow the connective tissue framework to reflect the architecture of the tissue in question. The arterial framework is beautifully illustrated in the corrosion cast studies of Last and Tompsett (see Fig. 21.2).^{2,85}

The cutaneous perforators exhibit the same pattern. They arise from their source artery (segmental or distributing artery) or one of its muscle branches and follow the intermuscular or intramuscular septa toward the surface (see Fig. 21.8). They pierce the deep fascia, branch, and ramify on its surface and ascend in the connective tissue framework of the superficial fascia, traveling between the fat locules to reach the subdermal plexus. During their course, the cutaneous vessels provide branches to the adjacent tissues, whether they are muscle, nerve, bone, fascia, or fat.

The cutaneous perforating veins can be traced in a retrograde fashion by means of the intermuscular and intramuscular septa to the outer layer of the deep fascia, where they usually form rich plexuses on either side of its surface. From there, they can be followed along the connective tissue framework of the superficial fascia, worming their way between the fat locules until they meet and become continuous with the horizontal plexus of large superficial veins near the dermis.

Arteries radiate from fixed to mobile areas and veins converge from mobile to fixed areas

Few arteries cross mobile tissue planes. Instead, they cross where tissues are anchored and radiate parallel to the plane of mobility, often for long distances. The cutaneous vessels pierce and emerge from the outer layer of the deep fascia near where it is anchored, either to its deep septa or to bone. The overlying integument is fixed also to the deep fascia at these sites. The fixed skin regions are seen easily in a well-muscled individual as grooves and valleys. They can be seen around the perimeter of muscles, especially where they interdigitate; over well-developed intermuscular septa; over the flexor surface of joints; adjacent to the dorsal and ventral midline of the body; around the base of the skull; and in the region of some bone prominences (see Fig. 21.16).

From the grooves and valleys in the deep fascia, the arteries flow toward the convexities of the body surface, branching within the integument. The wider the distance between the concavities and the higher the summit, the longer is the vessel. This pattern is well demonstrated in the blood supply to the integument of the scalp, nose, ears, breasts, and genitalia; the extensor surface of the joints; and the bulging surface of muscles (see Fig. 21.8).

Where the skin is relatively fixed to the deep fascia over a wide area (e.g., in the scalp and many areas of the limbs), the vessels remain close to the surface of the deep fascia for a considerable distance. In the loose skin areas of the body, especially over the pectoralis major muscle, the iliac fossa, and the extensor surface of joints, the vessels course for a short distance adjacent to the deep fascia. Soon they are plastered to the undersurface of the subcutaneous layer by a thin glistening sheet of fascia, and they then pierce the fat obliquely to reach the subdermal plexus, where they travel for long distances.

The veins course parallel to the plane of mobility, often for long distances, and cross where the tissues are anchored to fascia or bone. This is seen at the same site as the arteries.

BOX 21.1 Anatomic concepts

Vessels follow the connective tissue framework of the body

Arteries radiate from fixed to mobile areas and veins converge from mobile to fixed areas

Vessels “hitchhike” with nerves

Vessel size and orientation are the product of tissue growth and differentiation

Vessels interconnect to form a continuous three-dimensional network of vascular arcades

Vessels obey the law of equilibrium

Vessels have a relatively constant destination but may have a variable origin

Venous networks consist of linked valvular and avalvular channels that allow equilibrium of flow and pressure

Muscles are the prime movers of venous return

Within the subdermal plexus and in the subcutaneous fat, the veins and arteries often travel nearby at a distance and only come together when they pierce the outer layer of the deep fascia. Veins leave the subcutaneous tissue and pierce the deep fascia where the integument is anchored to it. This occurs around the perimeter of muscles, in particular where they interdigitate, over well-developed intermuscular septa. This is especially true in the limbs, where they are concentrated in longitudinal rows over the flexor surfaces of joints (e.g., the cubital fossa, axilla, popliteal fossa, and groin); adjacent to the dorsal and ventral midlines of the body; around the base of the skull and orbital margins where the galea is anchored; and where the deep fascia is fixed to bone, such as the subcutaneous border of the tibia (see Fig. 21.10).

In the deep tissues, veins leave muscles usually near their attachments to bone or fascia, most commonly on their deep surfaces. If a group of muscles has a common origin, for example, where the flexor and extensor muscles arise from the epicondyles of the humerus, the venous drainage of each is frequently collected into a large venous arch that courses in the muscle mass close to the bone.

It follows that, where a tissue is mobile over a long distance, whether muscle, skin, tendon, or nerve, large flaps are available for transfer and should be based on the fixed margin or end of that tissue. There are numerous situations in which this observation is used in everyday clinical practice. For example, the large axial skin flaps based on the fixed area of the groin, the paraumbilical region, and the parasternal region use the mobile skin areas over the anterior abdominal and chest walls. The commonly used muscle and tendon transfers are also based on this principle. If mobility exists between tissue planes, this provides a relatively avascular plane.

Vessels “hitchhike” with nerves

There is an intimate relationship between nerves and blood vessels throughout the deep tissues and the skin and subcutaneous tissues of the body, especially where a cutaneous nerve courses on the surface of the deep fascia. An artery may accompany the nerve for a considerable distance, often connecting with its neighbor in chain-link fashion to provide the basis for an axially oriented neurovascular flap. The cutaneous vessels and the nerve are occasionally in juxtaposition; in other situations, they course parallel to each other but at a distance. When the cutaneous nerve crosses a fixed skin site, it frequently “picks up” its next vascular companion (see Figs. 21.15, 21.16).

There are numerous instances throughout the body where this pattern of distribution of nerves and vessels exists to supply the integument. This includes the supraorbital, infraorbital, and occipital neurovascular bundles in the head; the supraclavicular nerves collecting branches of the suprascapular and supraclavicular vessels as they cross the clavicle on to the chest; the intercostal neurovascular bundles on the torso; and the cutaneous nerves of the arm, forearm, thigh, leg, and digits, which are accompanied by long named or unnamed vessels or a chain-linked system of vessels.

The cutaneous nerves are accompanied by a longitudinal system of arteries and veins that are often the dominant blood supply to the region. The veins in company with

the nerves are frequently large venous freeways, such as the cephalic, basilic, long saphenous, and short saphenous systems. The arteries either are long vessels (e.g., the supraorbital, lateral intercostal, or saphenous arteries) or exist as a chain-linked system of cutaneous perforators, often joined in series by true anastomoses without change in caliber (see Fig. 21.16).

The nerves pierce the deep fascia together with the vessels, they emerge separately and cross the vessels at an angle, or they approach the vessels from opposite directions. The main trunk of the vessel or some of its branches peels off to course parallel (see Fig. 21.15) to the nerve. These vessels either course in proximity to the nerve or travel nearby (see Fig. 21.16B).

This neurovascular relationship presents another basis for the design of long flaps with the added potential of providing sensation at the repair site. Many of the current “axial” or “fasciocutaneous” flaps are in fact neurovascular flaps. The original long and short saphenous flaps described by Pontén are examples.

Vessel growth and orientation are products of tissue growth and differentiation

Two centuries ago, John Hunter⁷⁶ suggested that at some stage of fetal development, there are a fixed number of arteries in the body. This has been the authors’ impression in comparing the number of cutaneous perforators encountered while raising the same flap in a child and in an adult. If this concept is correct, it provides a plausible explanation for the density and morphology of the cutaneous arteries in different regions of the body. It explains why vessels radiate from concavities and converge on convexities and why the vessels in some areas are small and close together, whereas in others they are large and spaced well apart (Fig. 21.39 ).

Fig. 21.39 appears online only.

There are numerous examples to support this hypothesis. The sternocleidomastoid and trapezius muscles split from the same somite.⁸⁶ The trapezius “drags” its supplying transverse cervical artery (and nerve) across the root of the neck to the back, together with a large band of skin that it nourishes. Manchot^{4,5} suggested that the long course and the direction of the superior and inferior epigastric arteries are brought about by the extension of the fetal torso. If one remembers that the cutaneous perforators pierce the deep fascia at fixed points and that they all interconnect, this would explain why, as the brain and skull expand, the scalp vessels hypertrophy and are stretched from the base of the calvaria toward its vertex.

The primitive cutaneous perforators in the fetus branch in all directions after piercing the deep fascia and have a stellate appearance. This pattern is retained into adulthood in many regions of the body. When a perforator departs from this pattern and becomes oriented in one direction, it highlights the differential increase in growth that has occurred along that axis or the influence of a developing cutaneous nerve. Where small perforators are clustered close together, this pattern suggests that, by comparison, the growth and hypertrophy in the area are less than at those sites where the perforators are large and spaced well apart. This is well demonstrated by comparing the perforators in the proximal and distal regions of the limbs.

Fig. 21.39 Diagram showing how the size and course of the direct cutaneous perforators x and y, which emerge from fixed points in the deep fascia, could be modified by growth either before or after birth. **(A)** The perforators, which are fixed in number and position, form a major connecting network on the surface of the deep fascia in the "resting state". **(B)** They are stretched with the deep fascia by the expansion of underlying tissues (e.g., the scalp vessels as the brain and skull expand during fetal development). **(C)** As the breast develops within the integument, the vessels are displaced toward the dermis and lengthened as they converge on the nipple. **(D)** They are stretched apart in the limbs as the long bones grow, but they still retain their original relationship to the deep fascia. **(E)** The vessels are again stretched apart by growth, but the mobile relationship between the undersurface of the integument and the deep fascia is responsible for their oblique course. This pattern is characteristic of the loose skin areas of the torso. (From Taylor GI, Palmer JH. *The vascular territories [angiosomes] of the body: experimental study and clinical applications*. Br J Plast Surg. 1987;40:113.)

Vessels interconnect to form a continuous three-dimensional network of vascular arcades

Arteries

Throughout the body, each vessel and its branches are connected with adjacent vessels and branches of neighboring vessels to form arches. The keystones in these arcades are formed sometimes by true anastomoses without change in caliber. More commonly, they are represented by reduced-caliber choke arteries and arterioles. The perimeter of choke or anastomotic vessels defines the anatomic territory of each artery (Fig. 21.40). Each vascular territory is surrounded by reduced-caliber choke anastomotic vessels. Thus, each tissue is supplied by a series of linked arterial territories, some small and some large.

Fig. 21.40 appears online only.

The concept is three-dimensional and was documented by Hunter in 1794.⁷⁶ He cited the vascular arcades in the hands and the feet as examples and stated that the arcades are smaller and occur more frequently as the arteries become more distal (Fig. 21.41). Thus, like a Roman aqueduct, the arterial framework consists of tiers of vascular arcades that commence from the aorta and become progressively smaller as the capillary bed is approached. In general, the large arcades are formed by the segmental or distributing source arteries (e.g., the intercostal, radial, ulnar, and deep epigastric arteries) that course between the tissues. Successive tiers of arcades are formed by the arteries, arterioles, and capillaries that supply those tissues.

Figs. 21.41–21.43 appear online only.

Veins

Commencing at the capillary bed, the venous arcades have a design similar to that of the arteries but in reverse, with the tiers

becoming larger and less numerous until the ultimate arcade is reached – the arcade represented by the superior and inferior venae cavae, with the heart situated at the keystone. These arcades link adjacent venous territories in and between tissues.

Within this network, there is a basic venous module that is repeated in the tiers of the venous network, modified in size and shape by the structure and function of the tissue and the embryologic growth and differentiation that have given rise to its adult form (Fig. 21.44A). It is stellate or medusoid in form and consists of a number of collecting veins that converge on a pedicle. A good example of this arrangement is the cartwheel of superficial veins that converge on the saphenous bulb in the groin. In some areas, the tributaries are polarized from one direction, like a tree that has been blown by the wind (Fig. 21.44B); this is true in the scalp, in muscles, and in the leg where the short saphenous vein approaches the popliteal fossa.

The branches within each “venous tree” are linked by channels, often free of valves, that are oriented like the rungs of a ladder or the circumferential loops of a cobweb. These arcades are well demonstrated in the hands, in the feet, in the cubital fossa, and between the venae comitantes that accompany the arteries. Peripherally, the radiating branches of each venous tree are linked to those of its neighbor, again by avalvular veins, to complete the network (Fig. 21.44C). In the integument, large horizontal channels have developed within this reticular framework to subserve the specialized function of thermoregulation (Fig. 21.44D). Their connections with the deep veins are retained as large channels, the venae communicantes, or by means of the smaller venae comitantes of the perforating cutaneous arteries (Fig. 21.45).

Vessels obey the law of equilibrium

This concept was described by Debreuil-Chambardel and is mentioned in Salmon’s description of the cutaneous arteries.^{8,10} Basically, this concept states that “the anatomical territories of

Fig. 21.44 Schematic diagrams of (A) the basic venous module, (B) its modified arrangement in different areas, and (C) how these modules interconnect to form a continuous network. (D) In the integument, this network of venous perforators is reorganized in the subdermal plexus to form longitudinal channels. The valved segments are solid blue, and the avalvular oscillating veins are light blue. (From Taylor GI, Palmer JH. *The vascular territories [angiosomes] of the body: experimental study and clinical applications*. Br J Plast Surg. 1987;40:113.)

The arterial arcades in the bowel mesentery are a classic example of vascular arcades in the body (Fig. 21.42). The arteries are smaller and more numerous as they approach the intestine. The basic pattern exists in all tissues and is modified by the morphology and function of that tissue. Even during tissue repair, the pattern of vascular arcades is reproduced in granulation tissue. Undoubtedly there are many reasons for the interconnections that exist between arteries, but almost

certainly one of these is to allow the equilibration of pressure across the arcades before the capillary bed is perfused.

Comparison of the vascular architecture in humans with that in other animals and other species reveals a similar arrangement of arcades. In the wings of insects and in the leaves of plants, the veins assume a pattern of interconnecting arcades similar to those of the intestinal mesentery (Fig. 21.43).

Fig. 21.45 Top: Schematic diagram of the integument and underlying muscle (shaded) in a limb illustrating the superficial (S) and deep (D) venous systems with their interconnecting network. A large vena communis (C) connects these systems, and the alternative pathways of four venae comitantes are shown. The valved veins are dark blue, and the oscillating veins are light blue. Bottom: Similar diagram representing other regions where the predominant venous drainage is by means of the venae comitantes. Note in each diagram that oscillating veins link adjacent territories in the integument and deep tissues. (From Taylor GI, Caddy CM, Watterson PA, et al. *The venous territories [venosomes] of the human body: experimental study and clinical implications*. *Plast Reconstr Surg*. 1990;86:185.)

adjacent arteries bear an inverse relationship to each other yet combine to supply the same region". If one vessel is small, its partner is large to compensate, and vice versa. This is well illustrated by the relative size of the superficial epigastric artery and the perforators of the deep inferior epigastric artery (DIEA). When the superficial inferior epigastric artery territory is noted to be large, the DIEA territory is relatively smaller, and vice versa (see Fig. 21.7). This is an important observation since, if a large superficial inferior epigastric vein is noted, the drainage of the inferior portion of the DIEAP flap may be dependent on the superficial venous drainage system.

Vessels have a relatively constant destination but may have a variable origin

This is typical of the vessels that emanate from the groin to supply the skin of the lower abdomen and upper thigh. The superficial inferior epigastric and the superficial circumflex iliac arteries, for example, may arise either separately from the common femoral artery or as a combined trunk from that vessel or from one of its branches. Whatever the case, their destination is constant to supply the integument of the lower abdomen and the hip (see Figs. 21.7, 21.16).

Venous networks consist of linked valvular and avalvular channels that allow equilibrium of flow and pressure

The venous network of the body is relatively poorly studied, compared to the arterial system. It consists of segments which

have consistent valves and numerous venous channels, large and small, that are free of valves and allow flow within their lumens in either direction. Conversely, there are many small veins that have valves at or near their ostia (sentinel valves) as they enter large channels (see Fig. 21.44).

Directional veins

Directional veins are valved veins which exist either as longitudinal channels, well developed in the subcutaneous and deep tissues of the limbs, or as a stellate pattern of collecting veins, which converge on a pedicle. The cutaneous perforators and the pedicle draining muscles are good examples of the latter arrangement. Because many of their tributaries have valves oriented distally as they converge on the pedicle, they provide the anatomic basis for distally based flaps (see Fig. 21.44).

Oscillating avalvular veins

Oscillating avalvular veins are avalvular vessels which are numerous and may reach large dimensions. They connect and allow free flow between the valved channels of adjacent venous territories, territories whose valves are oriented in the opposite direction (see Figs. 21.44, 21.45). They are also found between the valved channels of the same system; they match and accompany the choke arteries of the arterial framework. In the same way that the choke arteries define the arterial territories, oscillating veins define the perimeter of the venous territories (see Fig. 21.45). This is well illustrated in the study of the muscles (see Fig. 21.14) and in some areas of the integument, especially the torso, head, and neck. In the skin of the limbs, this pattern is overshadowed by the large superficial channels in the subdermal plexus but is apparent in cross-sectional studies. If one mentally subtracts the long, large venous channels from the picture in the limbs, the remaining stellate pattern of the perforating veins matches that of the perforating arteries. It is noteworthy that there is a rich network of large oscillating veins in the anterior thigh. This may provide an explanation for arterialized venous free flaps.

Muscles are prime movers of venous return

Most surgeons have been preoccupied with the arterial supply of the various muscles used for transfer. The efferent veins that accompany the arteries and drain the muscles have been noted and assumed, quite correctly, to be sufficient to provide an adequate venous return.

However, this is but half the picture. There are afferent veins entering almost every muscle in the body that arise from the overlying integument, adjacent muscles, and underlying bone where muscles are attached. When the muscles contract, valves in the efferent veins direct flow toward the heart. During "diastole", valves direct flow into the muscles by means of their afferent veins. If the valves in the muscles in the leg become incompetent (e.g., as the late result of deep venous thrombosis), it would not be difficult to envision the back-pressure effect on the afferent cutaneous veins entering the muscle and their role in the pathogenesis of varicose veins and venous ulceration.

Many veins connect muscle pairs or groups of muscles as arcades. It is noteworthy that the muscles with the richest afferent supply were those that filled most readily with our

injection studies. Notable examples are the gastrocnemius-soleus complex, the quadriceps muscles, the triceps, and the shoulder girdle muscles, especially the deltoid.

Superficial veins follow nerves and deep veins follow arteries

The venous drainage of the skin following investigation has been found to consist of two parts:

1. A subdermal horizontal network tends to follow the cutaneous nerves. This is seen in the limbs in particular, with named cutaneous nerves following named superficial veins (Fig. 21.46).
2. Where perforating veins pass through the deep fascia in a perpendicular fashion, this occurs with accompanying arteries. As stated in previous concepts, this usually occurs at fixed sites (see Fig. 21.39).

Applications of the angiosome concept

The vascular anatomical information contained in this chapter is an overview to provide the reader with general information important for the design of flaps. From our extensive anatomical studies, we have determined that the general vascular architecture of the body is consistent but variation between different individuals and from side to side in the same individual is the rule. As our understanding of the vascular anatomy of the human body improves, our ability to design and transfer flaps successfully is also improving. Although much is now known about the arterial framework of the body, the venous framework, and the nervous network, there are still gaps in our knowledge. Although knowledge of vascular

anatomy can be applied to all aspects of surgery, the primary focus in plastic and reconstructive surgery is often directed towards successful flap design. Therefore, the clinical applicability of this chapter pertains primarily to the identification of cutaneous perforators, their inclusion in flap design, and augmenting the blood flow of the vessels supplying the flap when necessary.

Preoperative assessment of the cutaneous vascular supply

Flap design

It has been determined clinically and experimentally that flaps can be safely designed by identifying a cutaneous perforator and an adjacent perforator; a line drawn between the two perforators should represent the axis of a viable flap.⁸⁷⁻⁸⁹ In the simplest situations, this approach can work well; however, the technique depends on a very accurate assessment of the cutaneous perforators.

Dopplers

A variety of Doppler ultrasound devices have been utilized to identify cutaneous vessels. The Doppler probe allows surgeons to locate cutaneous perforators with precision in individual cases. Using the knowledge that most cutaneous arteries emerge from fixed skin sites, as already outlined in the section on [anatomic concepts](#) (see Fig. 21.10), their expected origin can be anticipated and located rapidly. The simplest Doppler devices are handheld pencil Doppler probes.⁸⁷ These are easy to use, inexpensive, portable, and provide limited information (Fig. 21.47). All Dopplers require insight into their limitations. Dopplers may pick up background vessels and may not determine the course of vessels accurately. There is considerable inter-observer variability with the use of the Doppler. Obese patients in particular may limit its efficiency for two reasons. First, the thick cutaneous layer may preclude detection of the perforator as it emerges from the deep fascia. Second, as adipose tissue increases, the integument stretches into folds, and the course and destination of the perforators become distorted. However, a simple Doppler is a handy tool to identify cutaneous vessels accurately.

Fig. 21.47 appears online only.

The use of the Doppler probe to locate the origin of cutaneous perforators is not new and has been used by many in the past.⁸⁷ It is not necessary in every case, for obvious reasons. However, its application in free-flap transfer has been found to be invaluable, especially in siting a small flap. A good example of this is the osteocutaneous fibular flap, where just a small skin paddle(s) may be required as a part of the reconstruction. The Doppler probe is a quick, simple method for defining the perforators.

Color duplex Doppler

The more sophisticated Doppler devices are color duplex Dopplers which have greater resolution, cost, and inconvenience but provide much more detail on examination.⁹⁰⁻⁹² The color duplex ultrasound can accurately detect vessel diameter and flow velocity.⁹² Color duplex Doppler has advantages over CTA, including no intravenous contrast, lower cost, and

Fig. 21.47 Doppler probe for the design of skin flaps. The handheld Doppler can be used to identify cutaneous perforators for the design of skin flaps. In this case, the Doppler is used to design a flap based on perforators of the deep inferior epigastric vessels.

Fig. 21.48 Use of computed tomography angiography (CTA) in the planning of deep inferior epigastric artery perforator flaps. **(A)** Axial view of abdomen in patient preoperatively before deep inferior epigastric artery flap reconstruction of the breast. **(B)** Using CTA to plan surgery. Markings show perforators detected with handheld Doppler. **(C)** Grid overlay with white dots reflects radiologist's description of cutaneous perforators based on CTA using coordinates: R/L, distance from midline in millimeters, distance inferior to umbilicus, size of perforator in millimeters. (From Al-Dhamin A, Berry R, Prasad MA, et al. Coding system for computed tomographic angiography of inferior epigastric artery perforators in DIEAP flaps. *Plast Reconstr Surg.* 2012;129:387e–388e.)

no radiation exposure.⁹² The color duplex Doppler is usually already present in the radiology department of many hospitals but it generally requires training of a technician to obtain reliable and consistent results.

CT angiography

The most accurate method to determine the position, diameter, and course of perforators to the skin is CTA. Masia *et al.* initially reported the use of a multidetector CT scanner to map perforators prior to DIEAP flap harvest.⁹³ The CTA technique has become very popular and is now used around the world to define preoperatively the size, course, and details of individual perforators (Fig. 21.48). We have compared the accuracy of Doppler versus CTA and found CTA to be more accurate and more useful (see Fig. 21.48).⁹⁴ The high-resolution images of CTA provide extensive information for the surgeon regarding individual perforators as small as 0.3 mm.⁹⁵ In DIEAP flap reconstruction of the breast, we have developed a system to report individual perforators using a grid, thus enhancing

communication between radiologist and surgeon (see Fig. 21.48C). Also, in freestyle, perforator free-flap surgery,⁹⁶ knowledge of the perforator course prior to flap harvest can save a great deal of operating room time. The main disadvantages of CTA include cost and radiation exposure. Proponents of CTA highlight the savings gained by reducing operating room time. Also, radiation can be minimized by targeted examinations of the flap donor site. In addition, allergic reactions to contrast dye and claustrophobia are potential patient problems with CTA.⁹²

Axes of skin flaps

The cutaneous arteries of the skin have provided the basis of “axial” flaps used extensively in plastic and reconstructive surgery. Fig. 21.49 shows details of the origin, course, size, density, and interconnections of the cutaneous perforators. It therefore provides for the logical planning of the base and axis of a skin flap. Cross-sectional studies confirm the reason for including the outer layer of the deep fascia with flaps

Fig. 21.49 Some of the large axial cutaneous flaps that have been used or are available based on specific perforating arteries and their accompanying perforating veins, as defined by radiographic studies of the integument. In the scalp and the limbs, they should include the deep fascia. Compare with Figs. 21.10 and 21.16. (From Taylor GI, Palmer JH. *The vascular territories [angiosomes] of the body: experimental study and clinical applications*. Br J Plast Surg. 1987;40:113.)

raised in the scalp and in the extremities; in these situations, the vessels hug the fascia for considerable distances. If a flap is designed along the course of the cutaneous nerve, such as the saphenous or the sural nerve, long safe flaps can be and have been elevated. Pontén's²⁸ original flaps were designed in this way, and the saphenous neurovascular flap was planned in a similar manner.⁹⁷ In the loose skin areas of the torso, it is unnecessary to include deep fascia because the cutaneous arteries course at an early stage within the integument. They frequently correspond with the course of the cutaneous nerve.⁹⁸

Distally based skin flaps

Arterial perforators radiate in stellate patterns, and this includes branches that course proximally. The accompanying veins converge from the same directions. Hence, if a flap is based distally over such a perforating system, it will contain arterial branches that radiate proximally from it and valved veins that return to that point. Therefore, it has been noted that the presence of the perforator in the base of the flap is important and allows distally based flaps.^{99–101} An extension of this is the so-called propeller flap (Fig. 21.50), which is a local island fasciocutaneous flap based on a single dissected perforator.¹⁰² The propeller concept is an extension of the perforator flap concept. Basically, the most crucial element to the design of an adequately vascularized flap is the inclusion of a sufficient cutaneous perforator and its corresponding vein in the base of the flap. The flaps can be designed throughout the body in a wide variety of orientations as long as the vessel included as the flap vascular supply is not injured prior to or during the flap elevation and is not kinked. Therefore, gentle tissue handling and surgical technique are important to the success of propeller flaps and other local perforator flaps as well as releasing the deep fascia around the perforator to prevent kinking as the flap is rotated.

Skin flap dimensions

Because the blood supply of the integument, both venous and arterial, has been shown to be a continuous system of linked vascular territories, the survival length of a skin flap must depend on: (1) the caliber and length of the dominant vessels on which the flap is based; (2) the caliber and span of the adjacent captured artery or arteries, vein or veins; (3) the caliber and length of the connecting choke vessels; and (4) an anatomically favorable or unfavorable venous return; and the volume of flap tissue.

Where the arterial perforators are large and widely separated, the territory of each is large and a long flap can be raised with safety. These flaps are characteristic of the loose skin areas of the torso and the scalp. Conversely, if the perforators are small and located close together, the territory of

Fig. 21.50 Propeller flap. (A) The flap is likened to the blades of a propeller. (B) The flap is designed based on the largest adjacent uninjured perforator to the wound; $a = b + c + 1$ cm. (C) The flap is elevated based on the perforator. (D) The portion of the flap b is used to cover the donor site and the flap a is used to cover the wound. (From Teo TW. *The propeller flap concept*. Clin Plast Surg. 2010;37:615–626.)

each is small. The viable length of the flap is short unless the supplying source vessel is included in the design. This is evident in the fixed skin area of the sole of the foot.

If very large flaps are required or if vessels of a large caliber are necessary for microvascular anastomoses, the requirements can be satisfied by dissecting the perforators through the intermuscular septa or the intramuscular septa to include the underlying source vessels. The intelligent use of a delay also allows safe capture of adjacent vascular territories.

When we consider the venous drainage, the large longitudinal veins in the subcutaneous tissue of the limbs offer excellent venous drainage for proximally based flaps because their valves are oriented in that direction. However, in the lower abdomen, the drainage of proximally based flaps may be anatomically unfavorable because the valves of the superficial inferior epigastric veins are directed distally toward the groin. The undermined flap of a transverse abdominal lipectomy is a case in point, and perhaps fortuitously, the area of the flap in question is resected in the procedure.

The scalp veins are mostly free of valves, and hence flaps based in any direction will drain favorably. In many regions, however, the venous network consists of territories of valved veins oriented in different directions that are linked by oscillating veins.

The precise mechanism of the necrosis line of a flap is unknown, although the opening-up of arteriovenous shunts provides a plausible theory. Whatever happens, it has been shown that the choke vessels on the arterial side and some of the valved territories of the venous return provide a potential mechanical obstruction to flow.

Fasciocutaneous flaps

The deep fascia should be included in the design of the fasciocutaneous flap in those sites where the skin is relatively fixed to the deep fascia, for example, in the limbs or the scalp. In these instances, the dominant cutaneous vessels course on or lie adjacent to the deep fascia. Although they can be dissected free in some cases, it may be simpler and safer to include the deep fascia with the flap. However, where the skin and subcutaneous tissues are mobile over the deep fascia, for example, in the iliac fossae or the breast, it is unnecessary to include this fascial layer because the major cutaneous vessels have already left its surface. To some extent, the initial enthusiasm for fasciocutaneous flaps has been tempered by increased anatomical understanding and there are relatively few indications for the inclusion of deep fascia in a cutaneous flap.

The term “septocutaneous” is sometimes misleading, especially when it is used to describe a surgically created entity rather than a true anatomic structure. This may occur, for example, where the cutaneous perforators of a radial or ulnar flap are dissected within an envelope of loose areolar tissue. Furthermore, the septocutaneous flap may provide traps for the unwary surgeon. In some cases, the cutaneous artery and its accompanying vein leave the underlying source vessels and course toward the surface in a surgically favorable position, adjacent to a true white fibrous intermuscular septum. This is typical of the blood supply to the skin of the lateral arm flap, where cutaneous perforators arise from descending branches of the profunda brachii vessels and follow the lateral intermuscular septum toward the skin. This

pattern of supply usually exists where the muscles glide on either side of the intermuscular septum.

However, if the muscles attach to either side of the intermuscular septum, the cutaneous perforator may have a variable course. This variability is seen in particular in the lateral aspect of the upper calf. If a compound skin and bone flap is designed at this site over the lateral intermuscular septum based on the cutaneous perforators of the peroneal vessels, either these skin vessels may course directly to the surface, traveling in a favorable position, either adjacent to the septum or within the substance of the soleus or flexor hallucis longus muscles, close to their attachments to the fibula, or alternatively, they may arise indirectly from branches to the soleus or flexor hallucis muscles as terminal twigs of muscle branches that have arisen from the peroneal vessels at considerable distance from the lateral intermuscular septum. In these cases, a long and laborious intramuscular dissection of the cutaneous supply will be required to raise the flap successfully.

Musculocutaneous flaps

The musculocutaneous flap initially became popular when it was recognized that the large vessels supplying muscle were more reliable than the much smaller cutaneous vessels, and as a result the skin overlying the muscle was reliably transferred.^{23–26} Musculocutaneous flaps remain preferable in cases where large vascularized tissue bulk is required. However, it is now understood that the musculocutaneous perforators can be harvested without the bulk of the muscle as perforator flaps. When skin and deep fascia are firmly bound to the underlying muscle (e.g., the gluteus maximus and latissimus dorsi), the blood supply to the overlying skin is ensured. At each fixed site over the muscle, vessels emerge to supply the integument. However, when the muscle is mobile beneath the deep fascia (e.g., the gracilis muscle), the cutaneous supply is at most tenuous.

In general, musculocutaneous flaps can be raised safely if the skin paddle is placed over the perforators of the feeding muscle artery or those in the adjacent muscle territory. Attempts to capture territories beyond this, without previous delay, frequently result in vascular insufficiency. This situation may prevail, for reasons already outlined, in the pectoralis major and the pedicled TRAM flaps.

Depending on the muscle type and the site of the skin paddle, the venous pathway once again may become anatomically favorable or unfavorable. In each case, the venous drainage is thrust on perforators that drain to the intramuscular plexus of veins. In type I muscles, the drainage is favorable regardless of the site of the skin paddle over the muscle because the venous drainage is in one direction. If the skin paddle is placed over the distal territory of type II and type III muscles, the valves of this territory are oriented in the opposite direction to those of the draining pedicle, and the pathway is anatomically unfavorable. This problem was highlighted by Costa *et al.*¹⁰³ in their investigations of the venous drainage of the pedicled TRAM flap.

Many of the musculocutaneous flaps are being replaced by local or free microvascular perforator flaps based on the musculocutaneous perforators. These musculocutaneous perforators are variable in size and position and require a flexible operative approach. These “perforator flaps” are used

to provide large vessels for microvascular transfer; to eliminate the bulk of muscle, when appropriate; and to preserve muscle function, for example, in harvesting a lower transverse abdominal skin flap on one or more perforators of the deep inferior epigastric artery flap.^{38,39}

However, all cutaneous flaps are based on cutaneous perforators, whether direct or indirect, and regardless of whether they pass between or through the muscles to reach the overlying integument. Hence, to confine the term “perforator flap” to those instances in which the cutaneous vessel emerges from muscle to perforate the overlying deep fascia is misleading. The term “perforator flap” therefore should include any island skin flap, based on a cutaneous perforator, whether it arises from a source vessel between or within a muscle or other deep tissue. Some of the early free flaps, for example, the groin flap, are true perforator flaps, in this instance based on the superficial circumflex iliac or superficial inferior epigastric artery.²²

Perforator flaps

A perforator flap has been variously defined as a cutaneous flap based on a musculocutaneous perforator or any cutaneous flap based on any vessel supplying the skin.^{30,104–106} However, this is a semantic discussion which is not as important as the concept of perforator flaps, which represent the continuing evolution of tissue transfers. Initial pioneering reports of perforator flaps demonstrated that it was possible to harvest a skin flap reliably based on musculocutaneous perforators.^{38,107,108} Perforator flaps have the advantage of the large vessel size of vessels supplying muscles of the body without the disadvantages of unnecessary muscle bulk and the loss of function of unnecessary muscle sacrifice. The popularity of perforator flaps has increased exponentially, as evidenced by publications in the world’s plastic surgery literature, since the initial reports of this surgical technique.

Anatomical understanding has laid the groundwork for the success of perforator flaps.⁴⁷ Without detailed knowledge of the underlying vasculature, perforator flap surgery would be difficult. We have compiled an atlas of the perforators of the human body and subdivided their distribution into 61 vascular territories (Fig. 21.51).^{39,40,109} There are approximately 400 cutaneous perforators to the skin, about 60% musculocutaneous and 40% septocutaneous.^{39,40,109} The field has opened up significantly due to increased enthusiasm of surgeons to learn the “perforator flap technique” and increased flap options. Ultimately, perforator flaps have become more popular because patient outcomes have improved. Moreover, the emphasis on perforator flaps has focused attention on the vascular anatomy of the skin. Many of the 400 perforators to the skin can be used as a local or free-flap vascular supply, thus expanding the possible flap options dramatically. The use of the perforator flap technique allows clever and customized reconstructions which can provide optimal patient outcomes. However, perforator flaps are simply more flaps in the armamentarium of the plastic surgeon and good clinical judgment is still required to choose the best flap or technique for a specific application.¹¹⁰

The early pioneers of perforator flaps named flaps in a descriptive fashion which led to a wide array of terms to describe the flaps.^{104,110} In some cases, several terms were used for the same flap, which led to confusion and sometimes

delayed meaningful communication about the flaps.^{104,110} In an effort to standardize descriptions of perforator flaps, we introduced a nomenclature in which all perforator flaps are named according to the source vessel supplying the flap.³⁰ The letters AP are added to indicate artery perforator and the initials of the muscle through which the perforators travel are added as a suffix (Fig. 21.52). Hence, in the case of a DIEAP flap, DIEAP-ra (rectus abdominis). The suffix with muscle initials is only necessary when the perforating vessels can pass through different muscles. The suffix -s indicates that the perforator flap is a septocutaneous flap.

The choice of a suitable perforator and the dissection of the pedicle of a musculocutaneous perforator flap through a muscle require training, expertise, and gentle operative skills. Generally, the perforator flap is planned preoperatively using a handheld Doppler, a color duplex Doppler, or CTA.^{92,111} The largest perforator is usually chosen for the flap. As the flap dissection begins, each perforator over 0.5 mm in diameter is preserved until the pedicle is clearly visualized. As the dissection proceeds, gentle surgical technique is required, particularly at the fascial level, to avoid traction injuries to the small perforating vessels. Generally, the surgical technique is to skeletonize the vascular pedicle and keep the field dry.^{111,112}

Dozens of new perforator flaps have been described in the past decade. However, there is a core group of very useful perforator flaps which have become standard, including DIEAP flap,^{38,107,108} anterolateral thigh flap (based on the descending branch of the lateral circumflex femoral vessels through vastus lateralis, LCFAP-vl),¹¹³ submental artery flap (SMAP),¹¹⁴ posterior interosseous flap (PIOAP-s),¹¹⁵ thoracodorsal artery perforator flap (TAP-ld),¹¹⁶ superior gluteal artery (SGAP-gm),¹¹⁷ and inferior gluteal artery perforator flap (IGAP-gm).¹¹⁸ Depending on surgeon experience and preference, a number of these have replaced conventional flaps. The anterolateral thigh flap, in particular, has been called the ideal free flap, because of its usefulness in a wide variety of clinical applications.¹¹⁹ The perforator flaps are thoroughly described in a textbook on perforator flaps.³⁹ More recently, local perforator flaps have become increasingly utilized as a method of wound closure to provide tissues with good color match and contour and often avoid a free tissue transfer.^{120,121}

As Pribaz and Chan state, “The use of perforator flaps is a new and exciting paradigm in reconstructive surgery.”¹²²

The delay phenomenon

The only documented method to increase skin flap survival is the delay procedure. A delay procedure can be done in a variety of ways, from a partial incision around the margin of a planned flap, ligation of non-pedicle vessels supplying the flap, to partial or complete flap elevation (Fig. 21.53). The delay can be done in one or many stages and can lead to significantly improved skin flap survival. The physiologic effect of delay is an enlargement of the existing arteries along the axis of the flap, which has been well documented in experimental animal models (Figs. 21.54, 21.55).^{88,123,124} One adjacent anatomic vascular territory can be captured with safety on the cutaneous artery at the flap base. Anastomotic vascular keystones, usually formed by reduced-caliber choke arteries that link adjacent cutaneous perforators, play an integral role in the delay phenomenon. When a flap is elevated,

Fig. 21.55 Arteriogram of control (left) and delayed (right) rectus abdominis muscle of a dog 12 weeks after re-anastomosis of the previously ligated deep inferior epigastric artery (arrow). Note that the choke vessels remain tortuous and dilated, revealing that the effect of the delay is permanent and irreversible. (From Dhar SC, Taylor GI. *The delay phenomenon: the story unfolds*. *Plast Reconstr Surg*. 1999;104:2079.)

Fig. 21.51 Perforator vascular territories of the human body. The vascular territories of the body which correspond to regions of musculocutaneous and septocutaneous perforators to the skin. AIA, anterior interosseous artery; ATA, anterior tibial artery; BA, brachial artery; CSA, circumflex scapular artery; DCA, dorsal carpal arch; DCIA, deep, circumflex iliac artery; DGA, descending genicular artery; DIEA, deep inferior epigastric artery; DPA, dorsal pedis artery; DPAA, deep palmar arch; DPIA, dorsal branch of posterior intercostal artery; EPA, external pudendal artery; FA, facial artery; IGA, inferior gluteal artery; IOA, infraorbital artery; IPA, internal pudendal artery; ITA, internal thoracic (mammary) artery; IUCA, inferior ulnar collateral artery; LA, lumbar arteries; LCA, lateral calcaneal artery; LCFA, lateral circumflex femoral artery; LIGA, lateral inferior genicular artery; LPA, lateral plantar artery; LPIA, lateral branches of posterior intercostal artery; LSA, lateral sural artery; LSGA, lateral superior genicular artery; LTA, lateral thoracic (mammary) artery; MA, mental artery; MCA, medial calcaneal artery; MCFA, medial circumflex femoral artery; MIGA, medial inferior genicular artery; MSA, medial sural artery; MSGA, medial superior genicular artery; OCA, occipital artery; OPA, ophthalmic artery; PA, popliteal artery; PAURA, posterior auricular artery; PBA, profunda brachial artery; PCHA, posterior circumflex humeral artery; PFA, profunda femoris artery; PIA, posterior interosseous artery; PNA, peroneal artery; PRCA, posterior radial collateral artery; PTA, posterior tibial artery; RA, radial artery; RRA, radial recurrent artery; SCIA, superficial circumflex iliac artery; SEA, superior epigastric artery; SFA, superficial femoral artery; SGA, superior gluteal artery; SIEA, superficial inferior epigastric artery; SMA, submental artery; SPA, superficial palmar arch; STA, superficial temporal artery; STHA, superior thyroid artery; SUCA, superior ulnar collateral artery; TAA, thoracoacromial artery. (From Geddes CR. MSc thesis. Dalhousie University, Halifax, Nova Scotia, Canada.)

Fig. 21.52 Perforator flap nomenclature. (From Geddes CR, Morris SF, Neligan PC. Perforator flaps – evolution, classification and applications. *Ann Plast Surg*. 2003;50:90–99.)

Fig. 21.53 Diagrammatic representation of the same flap raised with and without a surgical delay to illustrate the necrosis line and the changes in the choke vessels. **(A)** The adjacent territory x is captured with safety, and the necrosis line occurs at the choke–vessel interface with vessel y or the one beyond. **(B)** Vessel x had been delayed. Note the effect on the choke vessels and the site of the necrosis line. **(C)** Vessels x and y have been delayed in this bipedicle flap. Vessel z is divided and the tip of the flap elevated at a second stage to provide the longest flap. (From Callegari PR, Taylor GI, Caddy CM, et al. *An anatomic review of the delay phenomenon I: experimental studies*. *Plast Reconstr Surg*. 1992;89:397–418.)

these choke vessels, which initially reduce flow from one arterial territory to the next along the flap, enlarge to the caliber of the cutaneous arteries they connect. However, this process of vessel enlargement is an active event and takes time. It is a permanent and irreversible process involving multiplication and hypertrophy of the cells in each layer of the vessel wall, with its maximal effect occurring between 48 and 72 hours after operation (Fig. 21.56).¹²³ It has been observed that necrosis usually occurs at the level of the next choke anastomosis in the arterial network or the one beyond. Surgically, flap survival can be extended by the strategic division of vascular pedicles at various time intervals along the length of the proposed flap – the “flap delay” procedure.

Composite flaps

A knowledge of the vascular supply of all the tissues that constitute each angiosome provides the basis for the transfer

Fig. 21.54 Arteriogram of control (left) and delayed (right) rectus abdominis muscles of a dog 7 days postoperatively. Note the dilated choke vessels in the delayed flap by ligation of the deep inferior epigastric artery (arrow). (From Dhar SC, Taylor GI. *The delay phenomenon: the story unfolds*. *Plast Reconstr Surg*. 1999;104:2079.)

of composite units of skin, muscle, nerve, tendon, and bone supplied by a single arteriovenous system. This knowledge has been applied extensively in free composite tissue transfer. The vessels within the angiosome interconnect between the various layers. This interconnection is well illustrated with the transfer of composite tissue from the groin region. The direct cutaneous perforators of the superficial circumflex iliac artery interconnect with the indirect perforators of the deep circumflex iliac artery. When a composite osteocutaneous flap is based on the deep system, the perforators of the deep circumflex iliac artery capture the territory of the superficial circumflex iliac artery to perfuse the skin.⁶⁶ When the superficial system is used, the reverse applies to perfuse the anterior segment of iliac crest and the attached muscles.⁶⁸

Angiosome concept and flap design

In this chapter, we have presented a variety of anatomical information which supports the angiosome concept and which provides a blueprint for successful flap design. As always in the course of surgical evolution, the ideas and concepts will gradually change to reflect new discoveries and the pioneering efforts of creative surgeons. Surgical advances move as the pendulum in an undulating course, ever closer to the true course.

Fig. 21.3 Carl Manhot's vascular territories of the human integument. **(A)** Cutaneous vascular territories, ventral surface. **(B)** Cutaneous vascular territories, dorsal surface. (From Manhot C. *Die Hautarterien des menschlichen Körpers*. Leipzig: FCW Vogel, 1889.)

Fig. 21.4 Michel Salmon's vascular territories of the human integument, 1936. Summary of the cutaneous arterial territories of the ventral surface of the body. (From Salmon M. *Artères de la peau*. Paris: Masson, 1936.)

Fig. 21.5 Cadaver with body landmarks and incision lines marked. (From Taylor GI, Palmer JH. The vascular territories [angiosomes] of the body: experimental study and clinical applications. *Br J Plast Surg*. 1987;40:113.)

Fig. 21.6 Lateral view of one female subject **(A)** and anterior view of another **(B)**. **(A)** The arm has been removed. Note the network of large vessels that sweep laterally from the ventral and dorsal midlines, ascend from the groins, descend from the shoulder girdle, and converge on the summits of the scalp and the breasts. This demonstrates the principle that vessels radiate from fixed concave zones and radiate to mobile convex areas. **(B)** A lower midline scar interrupts the vessels with compensatory opening of a large choke vessel above the umbilicus (arrow) to re-establish the flow across the midline. (From Taylor GI, Palmer JH. The vascular territories [angiosomes] of the body: experimental study and clinical applications. *Br J Plast Surg*. 1987;40:113.)

Fig. 21.56 Time sequence of delay. Immediately after the surgical elevation of a flap, the overall vascular diameter is reduced by vasoconstriction. Following this, gradual dilation occurs during the first 48 hours, and then dramatic dilation occurs from 48 to 72 hours. The rate of vessel enlargement then begins to plateau, and gradually, vessels increase thereafter.

Fig. 21.16 Arterial injection of the right upper limb and torso. **(A)** Note the chain-linked systems of arteries (arrows) that course with the cutaneous nerves in the upper limb. **(B)** On the torso, the nerves are marked on the arterial study. They course with the cutaneous arteries, cross them at angles and collect arterial branches, or approach the arteries from opposite directions (arrows). (From Taylor GI, Palmer JH. The vascular territories [angiosomes] of the body: experimental study and clinical applications. *Br J Plast Surg.* 1987;40:113; and Taylor GI, Gianoutsos MP, Morris SF. The neurovascular territories of the skin and muscles: anatomic study and clinical implications. *Plast Reconstr Surg.* 1994;94:1.)

Fig. 21.19 **(A)** Arteriogram of the skin of the pig. Note numerous small perforators on lateral torso, a superficial vein that has filled in the study (arrow), the larger segmental vessels near the ventral and dorsal midline, and the large perforator of the deep circumflex iliac artery near the hip. **(B)** Angiogram of the dog. Note the large perforator of the deep circumflex iliac artery and the thoracodorsal artery (arrows) near the hip and shoulder, respectively. **(C)** Arteriogram of the rabbit. Note the very large perforators of the deep circumflex iliac artery and thoracodorsal arteries dorsally and the superficial inferior epigastric artery and lateral thoracic arteries ventrally. Note also the large vessels supplying the ear. **(D)** Arteriogram of the duck. Note the discrete territories bounded by choke arteries and the long, stretched-out perforator of the transverse cervical artery in the mobile skin area of the neck (arrow). (From Taylor GI, Minabe T. The angiosomes of the mammals and other vertebrates. *Plast Reconstr Surg.* 1992;89:181.)

Fig. 21.20 Injection studies of the anterior torso with the integument removed and umbilicus located (large dot). The studies of the human and dog **(A and C)** are almost identical, with the deep inferior epigastric artery larger than the deep superior epigastric artery. In the pig and rabbit **(B and D)**, the reverse applies. (From Taylor GI, Minabe T. The angiosomes of the mammals and other vertebrates. *Plast Reconstr Surg.* 1992;89:181.)

Fig. 21.21 Comparative study of the rectus abdominis muscle from the various mammals studied. There is a striking similarity between the studies. However, in all animals except the pig, the muscle extends on to the thorax more cranially than in the human, and this region of the rectus receives additional branches from the internal thoracic artery. The reciprocal size relationship of the deep superior epigastric artery and deep inferior epigastric artery between species is a good example of the law of equilibrium. (From Taylor GI, Minabe T. The angiosomes of the mammals and other vertebrates. *Plast Reconstr Surg.* 1992;89:181.)

Fig. 21.26 The cutaneous perforators of the forearm, color-coded to match the angiosomes. Large and small skin perforators are indicated by size of the colored markers. Compare with **Fig. 21.22**. (From Inoue Y, Taylor GI. The angiosomes of the forearm: anatomic study and clinical applications. *Plast Reconstr Surg.* 1996;98:195.)

Fig. 21.27 The vascular territories of the **(A)** superficial, **(B)** middle, and **(C)** deep forearm flexor muscles. Note that the junctional zone between angiosomes occurs primarily within the muscles and that most muscles cross at least two angiosomes. Compare with **Figs. 21.23** and **21.24**. (From Inoue Y, Taylor GI. The angiosomes of the forearm: anatomic study and clinical applications. *Plast Reconstr Surg.* 1996;98:195.)

Fig. 21.28 The vascular territories of the **(A)** superficial and **(B)** deep forearm extensor muscles, showing once again that the junctional zone lies primarily within the muscles. (From Inoue Y, Taylor GI. The angiosomes of the forearm: anatomic study and clinical applications. *Plast Reconstr Surg.* 1996;98:195.)

Fig. 21.29 Cross-sectional studies of the forearm at the level of **(A)** the head of the radius, **(B)** insertion of the pronator teres, and **(C)** midforearm, showing the angiosomes of the forearm: brachial (yellow), radial (blue), ulnar (red), anterior interosseus (green), and posterior interosseous (orange) arteries. Note that the junctions of the angiosomes occur within the skin, within the muscles, and within the bone. (From Inoue Y, Taylor GI. The angiosomes of the forearm: anatomic study and clinical applications. *Plast Reconstr Surg.* 1996;98:195.)

Fig. 21.30 Vascular territories of the lower leg. The colored circles represent cutaneous perforators emerging from the deep fascia and depict relative size of the vessels. (From Taylor GI, Pan WR. The angiosomes of the leg: anatomic study and clinical applications. *Plast Reconstr Surg.* 1998;102:599.)

Fig. 21.31 Vascular territories of the lower leg. **(A)** Illustration of the anterior muscle group that lies totally within the anterior tibial angiosome (blue). This angiosome extends to include part of the peroneal muscles. **(B)** Illustration of the lateral muscles and their supply from the anterior tibial (blue) and peroneal (green) angiosomes. (From Taylor GI, Pan WR. The angiosomes of the leg: anatomic study and clinical applications. *Plast Reconstr Surg.* 1998;102:599.)

Fig. 21.32 Vascular territories of the lower leg. **(A)** The superficial muscle group with its supply from the arteries of the popliteal (purple), sural (orange), posterior

tibial (yellow), and peroneal (green) angiosomes. All muscles cross at least two angiosomes and receive branches from the source arteries of each. **(B)** The deep muscles and their supply form the source arteries of each angiosome. (From Taylor GI, Pan WR. The angiosomes of the leg: anatomic study and clinical applications. *Plast Reconstr Surg.* 1998;102:599.)

Fig. 21.33 **(A–C)** Vascular territories of the lower leg. Anterior view of the leg with cross-sections at three levels, viewed distally. The figures show angiosomes of the anterior tibial (blue), posterior tibial (yellow), peroneal (green), and sural (orange) arteries. Note in each case that the angiosome territories extend from the skin to the bone and that their borders, defined by anastomotic vessels, meet usually within tissues, especially the muscles, rather than between them. (From Taylor GI, Pan WR. The angiosomes of the leg: anatomic study and clinical applications. *Plast Reconstr Surg.* 1998;102:599.)

Fig. 21.34 Fresh cadaver lead oxide arterial study of the lateral **(A)** and anterior **(B)** view of the composite skin and superficial musculoaponeurotic system (SMAS) unit in the head and neck. The occipital (a), superficial temporal (b), and ophthalmic (c) arteries have been labeled. Note that the facial vein (v) runs a more direct course and at some distance to its arterial counterpart, the facial artery (d). **(C)** The skin layer alone reveals a vast arterial “blush” zone of the skin and SMAS shown in sagittal view. Note: (1) the rich arterial anastomotic “waves” formed between the branches of the occipital, superficial temporal, and ophthalmic arteries in the scalp; (2) the cluster of small vessels supplying the fixed skin area over the parotid gland and masseter muscle compared with the large branches of the facial artery that supply the mobile anterior face; and (3) the relative paucity of large vessels in the neck except in the anterior triangle. The SMAS layer is seen only in **(D)** with the muscles of facial expression outlined. (From Houseman ND, Taylor GI, Pan WR. The angiosomes of the head and neck: anatomic study and clinical applications. *Plast Reconstr Surg.* 2000;105:2287.)

Fig. 21.35 **(A)** Lead oxide arterial study of the blood supply of the ear and adjacent tissues. Note the arcades formed between the superficial temporal and posterior auricular arteries, highlighted with arrows. **(B)** Schematic picture shows the branches of the superficial temporal (dark) and posterior auricular (light) supply to the front and back of the ear, respectively. Note also the true and choke anastomoses between these two arteries in the scalp. **(C, D)** Close-up examination of the arterial anatomy of the external nose. Note the arcades that occur around the alar dome between the columella branch of the superior labial artery and the facial artery. The facial vein has also been partially filled with lead oxide and highlighted by the arrows. (From Houseman ND, Taylor GI, Pan WR. The angiosomes of the head and neck: anatomic study and clinical applications. *Plast Reconstr Surg.* 2000;105:2287.)

Fig. 21.36 Angiosomes of the muscles of facial expression and mastication in the face. (From Houseman ND, Taylor GI, Pan WR. The angiosomes of the head and neck: anatomic study and clinical applications. *Plast Reconstr Surg.* 2000;105:2287.)

Fig. 21.37 **(A–D)** The angiosomes of the head and neck colored and numbered to match **Figs. 21.22** and **21.35**. (From Houseman ND, Taylor GI, Pan WR. The angiosomes of the head and neck: anatomic study and clinical applications. *Plast Reconstr Surg.* 2000;105:2287.)

Fig. 21.38 Radiograph of the tongue; note the almost avascular midline. (From Houseman ND, Taylor GI, Pan WR. The angiosomes of the head and neck: anatomic study and clinical applications. *Plast Reconstr Surg.* 2000;105:2287.)

Fig. 21.39 Diagram showing how the size and course of the direct cutaneous perforators x and y, which emerge from fixed points in the deep fascia, could be modified by growth either before or after birth. **(A)** The perforators, which are fixed in number and position, form a major connecting network on the surface of the deep fascia in the “resting state”. **(B)** They are stretched with the deep fascia by the expansion of underlying tissues (e.g., the scalp vessels as the brain and skull expand during fetal development). **(C)** As the breast develops within the integument, the vessels are displaced toward the dermis and lengthened as they converge on the nipple. **(D)** They are stretched apart in the limbs as the long bones grow, but they still retain their original relationship to the deep fascia. **(E)** The vessels are again stretched apart by growth, but the mobile relationship between the undersurface of the integument and the deep fascia is responsible for their oblique course. This pattern is characteristic of the loose skin areas of the torso. (From Taylor GI, Palmer JH. The vascular territories [angiosomes] of the body: experimental study and clinical applications. *Br J Plast Surg.* 1987;40:113.)

Fig. 21.40 Dotted line through choke connecting vessels of a large acromioclavicular perforator to define its anatomic territory. Compare with **Fig. 21.16**, left side of chest. (From Taylor GI, Palmer JH. The vascular territories

[angiosomes] of the body: experimental study and clinical applications. *Br J Plast Surg*. 1987;40:113.)

Fig. 21.41 Radiographs of the integument of the upper limb and hand. (A) The skin has been incised along the ulnar border. It has been removed (B) with the deep fascia and (C) without it. (From Taylor GI, Palmer JH. The vascular territories [angiosomes] of the body: experimental study and clinical applications. *Br J Plast Surg*. 1987;40:113.)

Fig. 21.42 The interconnecting arcades of the small intestine. (From Crosthwaite GL, Taylor GI, Palmer JH. A new radio-opaque injection technique for tissue preservation. *Br J Plast Surg*. 1987;40:497.)

Fig. 21.43 (A) The wing of a moth and (B) the leaf of a tree, showing their interconnecting arcades of "veins". (From Taylor GI, Palmer JH. The vascular territories [angiosomes] of the body: experimental study and clinical applications. *Br J Plast Surg*. 1987;40:113.)

Fig. 21.47 Doppler probe for the design of skin flaps. The handheld Doppler can be used to identify cutaneous perforators for the design of skin flaps. In this

case, the Doppler is used to design a flap based on perforators of the deep inferior epigastric vessels.

Fig. 21.55 Arteriogram of control (left) and delayed (right) rectus abdominis muscle of a dog 12 weeks after re-anastomosis of the previously ligated deep inferior epigastric artery (arrow). Note that the choke vessels remain tortuous and dilated, revealing that the effect of the delay is permanent and irreversible. (From Dhar SC, Taylor GI. The delay phenomenon: the story unfolds. *Plast Reconstr Surg*. 1999;104:2079.)

Fig. 21.56 Time sequence of delay. Immediately after the surgical elevation of a flap, the overall vascular diameter is reduced by vasoconstriction. Following this, gradual dilation occurs during the first 48 hours, and then dramatic dilation occurs from 48 to 72 hours. The rate of vessel enlargement then begins to plateau, and gradually, vessels increase thereafter.

Flap classification and applications

Joon Pio Hong

 Access video lecture content for this chapter online at expertconsult.com

SYNOPSIS

- Flap is tissue(s) with its own vascular supply, allowing transfer from one site to another.
- Flaps come in various forms, shapes and function. They may be composed of a simple skin tissue or multiple composite tissues.
- The purpose of classification is to understand the anatomy and the features that each flap provides. It also allows communication not only with peers but with the patients as well to achieve the common goal of reconstruction.
- Various methods can be used to classify flaps, but commonly used classifications are based on the locality of the flap, vascular supply of the flap, and tissue components of the flap.
- By applying a precise knowledge of the anatomy of skin, muscle, bone, fascia, and other tissue in planning reconstructive procedures, the surgeon has the ability to restore function in congenital and acquired defects.
- This chapter reviews flap classification and gives examples of its applications.

History

The use of flaps for reconstructive plastic surgery dates back to 600 BC, when the earliest recorded application of pedicled flaps for nasal reconstruction is attributed to Sushruta Samhita (translated by Bhishagratna in 1916).¹ The earliest flaps centered on the head and neck as well as the lower extremities because wounds in these regions failed to heal by secondary intention. The initial flaps used would now be considered random-pattern flaps, as they were not based on a specific blood supply and were used without an understanding of how and why they survived. All possible flaps were based on the simple idea of random flaps.² Tagliacozzi used a distally-based arm flap in a two-staged procedure.³ His work was published in Venice in 1597. Much of this knowledge was forgotten until the 19th century, when the English surgeon Carpie successfully used forehead flaps to reconstruct the

noses of two officers.⁴ The publication of *Rhinoplastik* by von Graefe in 1818 further advanced the use of these techniques.⁵ Attention in the early 20th century remained focused on tubed random flaps. It was found that the only way to increase survival of these flaps was to perform a surgical delay. A German anatomist, Carl Manchot, demonstrated the concept of anatomic skin territories supplied by consistent vessels in *Die Hautarterien des Menschlichen Körpers*, published in 1889.⁶ Further development into the shape of modern flaps came with Tansini when he described the skin island of the latissimus dorsi musculocutaneous flap in 1906.⁷ Davis, crediting Manchot, demonstrated axial and pedicled muscle and fascial flaps, as well as composite flaps in 1919.⁸ McGregor introduced the temporalis flap, which allowed midface and lower face coverage without the donor site deformity associated with the previously popular forehead flap.⁹ Coverage of the lower third of the face as well as of the oral and esophageal defects was accomplished by Bakamjian with the use of the deltopectoral flap.¹⁰ The availability of the forehead, temporalis, and deltopectoral flaps changed the approach to head and neck cancer extirpative surgery with an emphasis on immediate reconstruction. A slow evolution of flaps was based on experience and gradual understanding of anatomy.

The muscle flap for lower extremity reconstruction was initially described by Stark for coverage of debridement sites for osteomyelitis.¹¹ Unfortunately, this went unnoticed until Ger recognized that the leg muscles are a source of well-vascularized tissue for leg coverage.¹² Although Owens, in 1955, used a compound flap consisting of the sternocleidomastoid muscle with overlying skin for head and neck reconstruction, the concept of musculocutaneous perforating vessels providing a cutaneous territory for superficial muscles was first reported by Orticochea in 1972.¹³ Shortly thereafter, surgeons made significant contributions toward definition of flaps, expansion, and use of muscle and musculocutaneous flaps in reconstructive surgery. The contributions included the concept of cutaneous territory of superficial muscles;¹⁴ anatomy of the muscles including specific arcs of rotation;^{15,16} applications of muscle and musculocutaneous flaps for breast,

chest, extremity, and head and neck reconstruction; and microsurgical transplantation.^{17–22} In 1981, Ponten recognized the input of septocutaneous perforating vessels to the overlying skin circulation.²³ On the basis of this observation, the concept of fasciocutaneous flaps was introduced. Like the muscle flap, the septocutaneous flap was initially described in the lower extremity, but the principle of the fasciocutaneous flap, based on muscle, fascia, and associated cutaneous territories, was rapidly applied to all body regions (Table 22.1).

Starting in the late 1970s, a proliferation of innovative techniques reported in the surgical literature throughout the world defined new anatomic data and applications of the muscle, musculocutaneous, fascial, and fasciocutaneous flaps. These advances in flap definition and application have changed the entire approach to plastic surgery. With the isolation of the vascular pedicles to muscle- and fascia-based flaps, microsurgical transplantation is selected when the ideal flap is outside of a traditional and safe arc of rotation to the recipient site. With the definition of musculocutaneous and fasciocutaneous territories, an expander may be used to enlarge flap dimensions and still ensure direct closure of the donor site. The reconstructive ladder, introduced in 1982, was appropriate for use in choosing reconstructive methods that ensure safety in soft-tissue reconstruction.²⁴ With increased understanding of the flap anatomy, physiology and even in regards to donor morbidity, ideal form and function can be achieved by complex procedures without compromising safety. This new approach can be considered as an elevator approach to defects entailing most of the issues to achieve a minimal

staged and ideally functional reconstruction.²⁵ Furthermore, donor site deformity is frequently avoided because the flap can be precisely tailored to fit the defect. In 1997, the reconstructive triangle was introduced to guide the thinking of complex reconstruction.²⁶ The surgeon may choose the transposition flap, microsurgical transplantation, or tissue expansion with the goals of achieving form and function at the recipient site, avoiding donor site deformity, and providing safety throughout the reconstructive endeavor. The more recent introduction of perforator flaps has expanded our options even more and brought us to the era of free-style flaps.²⁷ With all the explosive introduction of new flaps, new ideas and new findings, a classification may not describe all the innovations involved in the field of reconstruction. Furthermore, the introduction of the corresponding ideas and nomenclature increases the confusion.

This chapter describes the flap classification based on the important characteristics of the flap. The atomic classification of Tolhurst naturally involved the early flap characteristics and further refinements from Lamberty and Healy describe the most important factors for flap selection; circulation, constituents, conformation, contiguity, construction, and condition.^{28,29} Further modifications have been made to accommodate the recent introduction of flaps. In addition, application of these flaps will be introduced in this chapter.

Classification of flaps

A flap consists of tissue that is mobilized on the basis of its vascular anatomy. Flaps can be composed of skin (including subcutaneous fat), skin and fascia, skin and muscle, or skin, muscle and bone, or various compositions of tissues. Because the circulation to the tissue to be mobilized is crucial for flap survival, the development of flap techniques has depended on defining the vascular anatomy of the skin and underlying soft tissue.

The first classification can be made for a random pattern flap with a non-identified pedicle versus flaps with an identified pedicle. An early concept of vascular anatomy as it pertained to flap surgery was the belief that skin circulation was based on the longitudinal subdermal plexus. A random pattern flap based on this subdermal plexus was designed to allow elevation of skin and subcutaneous tissue with a certain length:width ratio in the range of 2–1.5:1. Based on the simplicity of circulation, the shape and movement of the flap were important distinguishing factors (Fig. 22.1). Milton subsequently disproved the concept of length-to-width ratios as viability depended on the extent of circulation.³⁰ He further proved his concept by showing that a delay procedure on the flap can further increase the extent of the flap in a pig model.³¹ Historically, attempts to use a random pattern flap based on subdermal circulation distant from the wound location eventually resulted in the introduction of the tubed pedicle flap. Through a series of delays using the initial bipedicle flap design, the arc of rotation of the skin flap was increased. Alternatively, the flap was attached to an arm carrier, which later required transferring the arm carrier of the random pattern flap from one body region (donor site) to another (recipient site). This use of the random pattern flap with multiple delays or the arm carrier allowed reconstruction of distant complex defects, particularly in the head and neck

Fig. 22.3 Updated modified “atomic system” with “six Cs” of flap characteristics, but especially “core” or source of flap circulation, where each has a distinct role in determining flap nomenclature. (From Hallock GG. *The complete classification of flaps*. Microsurgery. 2004;24:157–161.)

toward the defect with minimal tension. Because of the large size of the flap, identification of the vascular source is not necessary and it is presumed to have various blood supplies from the perforators entering from the deep fascia. But when perforators are identified using a Doppler, one can also call this a keystone-design perforator island flap.³²

Previously with random pattern flaps, type of movement, shape of the flap or anatomical region was the focus for differentiating the types. But as the anatomy of the vessel became more evident and the importance recognized, flap description began to depict the circulation.²⁸ The evolution from random pattern flaps to fasciocutaneous flaps, myocutaneous flaps and then recently to perforator flaps was based on the development and findings of vascular anatomy throughout the body. Pioneering work from Manchot, Salmon, Cormack, Lamberty, Taylor, Morris, Tang, Nakajima and others clarified the vascular anatomy for skin territory originating from a source vessel.^{6,29,33–37} The flap elevation practice changed with the work of Taylor and Palmer presenting the angiosome concept, which increased our knowledge of vascular territory of the skin flap.³³ Now the concept of vascular territory has evolved from thinking of the angiosome as the basic unit to applying the perforator as the basic unit, termed “perforasome”.³⁸

Circulation being clearly the most important characteristic of flaps with identified pedicle, Cormack and Lamberty were the first to advocate the source of the circulation as the most important characteristic of flap selection.²⁹ The six Cs included, in addition to circulation, constituents (composition), conformation (form/shape), contiguity (destination), construction (type of pedicle), and conditioning (preparation) (Fig. 22.3). Hallock further outlined this classification in accordance with the six Cs and named it “complete classification of flaps”.³⁹ With the addition of recent flaps and advances, a modified outline for the basis of flap classification is shown in Table 22.2.

This approach to muscle flaps can be demonstrated with the gracilis muscle flap shown in Fig. 22.4:

- Circulation: medial circumflex femoral artery
- Constituents: gracilis muscle
- Contiguity: free flap
- Construction: antegrade flow

Table 22.2 The basis for flap classification

1. Circulation (blood supply)

Direct vessels
axial
septocutaneous
endosteal
Indirect vessels
myocutaneous
periosteal

2. Constituents (composition)

Skin (with subcutaneous fat)
Fasciocutaneous/fascia
Muscle/musculocutaneous
Visceral
Nerve
Bone
Cartilage
Lymph node (with subcutaneous fat)
Other

3. Contiguity (destination)

Local
Regional
Distant (free)

4. Construction (flow)

Unipedicle*
Bipedicle
Antegrade*
Retrograde (reverse)
Turbocharged
Supercharged
Arterialized venous

5. Conditioning

Delay
Tissue expansion
Prefabrication
Sensate (sensory nerve)
Functional (motor nerve)
None*

6. Conformation

Special shapes
Tubed
Combined flaps
None*

*Denotes default or standard for flaps and can be omitted in the use of complete classification.

- Conditioning: none
- Conformation: muscle only

Thus the gracilis muscle flap from Fig. 22.4 can be named medial circumflex femoral artery-based (circulation) gracilis muscle (constituents) free (contiguity) flap with antegrade flow (construction) with no conditioning (conditioning) and muscle only (conformation) according to the complete classification. But, as default, “antegrade flow with no conditioning” can be omitted from the nomenclature. Also, since there is one conformation, “muscle” does not have to be repeated and, finally, since the circulation from the “medial circumflex

Fig. 22.4 Example of a gracilis muscle flap. It can be named a medial circumflex femoral artery-based (circulation) gracilis muscle (constituents) free (contiguity) flap with antegrade flow (construction) with no conditioning (conditioning) and muscle only (conformation) according to the complete classification.

femoral artery” is an established one for any muscle flaps, this can be considered to be understood and does not have to be reiterated. Thus the final classification using the “complete classification” can be described as “gracilis muscle free flap”.

For muscle flaps, the circulation can be from multiple variations and these variations play an important part in survival of each muscle flap. Therefore further classification of muscle flaps should be addressed.¹⁶

The next example would be a musculo-fascio-cutaneous flap from the same region as shown in Fig. 22.5:

- Circulation: medial circumflex femoral artery
- Constituents: gracilis muscle and upper medial thigh fasciocutaneous
- Contiguity: free flap

Fig. 22.5 Example of a musculo-fascio-cutaneous flap including the gracilis muscle and the combined skin and fascia.

- Construction: antegrade flow
- Conditioning: none
- Conformation: combined muscle and fasciocutaneous flap

The flap in Fig. 22.5 can be named as medial circumflex femoral artery-based (circulation) gracilis muscle (constituents) free (contiguity) flap with antegrade flow (construction) with no conditioning (conditioning) and combined with muscle and fasciocutaneous component (conformation) according to the complete classification. As defaults are omitted from the nomenclature, the “complete classification” should be: “combined gracilis musculo(-fascio-)cutaneous free flap”.

The actual source of circulation feeding the subdermal plexus of the skin was described in a tripartite system from Cormack and Lamberty.²⁹ The system consisted of axial (direct cutaneous), musculocutaneous, and fasciocutaneous types of free flaps. They further described the fasciocutaneous flap into subtypes leading to the fasciocutaneous flap classification.⁴⁰ These classifications should be recognized as they rely on the anatomical vascular system of the flap and improve the design and survival of the flaps.

When the skin portion of this flap is isolated on a single perforator, the constituents become a combination of medial circumflex artery perforator flap and gracilis muscle flap. Combined flaps with identified circulation can also undergo a classification for combined/compound flaps.^{41,42} Thus, this variation of flap should be named “combined (conjoint) medial circumflex femoral perforator and gracilis muscle free flap”.

The final example is shown in Fig. 22.6. Note that this flap from the upper medial thigh is supplied only with a perforator.

- Circulation: medial circumflex femoral artery (perforator)
- Constituents: upper medial thigh skin (with fat)

Fig. 22.6 Example of flap from the upper medial thigh, supplied only with a perforator without the gracilis muscle and the fascia.

Fig. 22.7 Mathes–Nahai classification of muscle and musculocutaneous flaps.

- Contiguity: free flap
- Construction: antegrade flow
- Conditioning: none
- Conformation: skin (with fat) only

The circulation to this flap is the same source vessel as the gracilis muscle or musculocutaneous flap. But this is a flap supplied with an identified perforator, so recognition should be made of the perforator as the main circulation. Thus, this flap should be named as “medial circumflex femoral artery perforator-based (circulation) upper medial thigh skin (with fat) (constituents) free (contiguity) flap with antegrade flow (construction) with no conditioning (conditioning) and skin only component (conformation) according to the complete classification. As defaults are omitted from the nomenclature, the “complete classification” should be “medial circumflex femoral artery perforator skin flap”.

This type of perforator-based flap has been subject to controversy as there have been many classifications proposed. The Gent consensus for classification of perforator flaps will be reviewed as an example of perforator flap classification.

Flaps based on the constituents

Muscle and musculocutaneous flaps

In 1981, Mathes and Nahai described a classification system for muscles based on the following anatomic relationships between the muscle and its vascular pedicles:

1. The regional source of the pedicle entering the muscle
2. The number and size of the pedicle
3. The location of the pedicle with respect to the muscle’s origin and insertion

4. The angiographic patterns of the intramuscular vessels.

This classification system enables the surgeon to categorize the various muscle and musculocutaneous flaps into distinctly different, clinically applicable groups based on the vascular anatomy. There are five different vascular patterns by which the various muscles are categorized (Fig. 22.7).¹⁶

Type I: one vascular pedicle – Type I muscles are supplied by a single vascular pedicle (Table 22.3).

Type II: dominant vascular pedicle and minor pedicle – Type II muscles are supplied by both a dominant and minor vascular pedicle. The larger dominant vascular pedicle will usually sustain circulation to these muscles after the elevation

of the flap when the minor pedicles are divided. This is the most common pattern of circulation observed in human muscle (Table 22.4).

Type III: two dominant pedicles – Type III muscles possess two large vascular pedicles from separate vascular sources. These pedicles have either a separate regional source of circulation or are located on opposite sides of the muscle. Division of one pedicle during flap elevation rarely results in loss of muscle within its vascular distribution. The muscle will usually survive on one of its two dominant vascular pedicles.

This vascular pattern allows the muscle to be split, allowing the use of only part of the muscle as a muscle or musculocutaneous flap (Table 22.5).

Type IV: segmental vascular pedicles – Type IV muscles are supplied by segmental vascular pedicles entering along the course of the muscle belly. Each pedicle provides circulation to a segment of the muscle. Division of more than two or three of the pedicles during elevation as a flap may result in distal muscle necrosis (Table 22.6).

Type V: one dominant vascular pedicle and secondary segmental vascular pedicles – Type V muscles are supplied by a single dominant pedicle and secondary segmental vascular pedicles. These muscles have one large dominant vascular pedicle near the insertion of the muscle with several segmental pedicles near the origin. The internal vasculature can be supplied by either the dominant or the segmental pedicles, and therefore the muscle may be elevated as a flap on either vascular system (Table 22.7).

When a flap is used based on the pedicle as a local or an island flap, the dominant vascular pedicle to the flap is preserved. A factor that may prevent successful flap transposition is the flap's arc of rotation. The arc of rotation of a muscle is determined by the extent of elevation of the muscle from its anatomic bed and the ability of the muscle to reach adjacent areas without devascularization. The mobility of a muscle depends on the number of vascular pedicles and the location of the dominant vascular pedicle relative to the muscle's origin and insertion (Fig. 22.8). The area covered by the arc of rotation varies among individuals. On the basis of the flap

Fig. 22.8 Arc of muscle rotation (latissimus muscle).

length distal to the point of rotation and the length of the vascular pedicle, a safe standard arc of rotation is measured for each flap. A modified arc of rotation is also available based on refinements in design and specific modifications of the flap. Precise knowledge of the safe standard and modified arc of rotation is necessary to avoid loss of the flap from excessive tension or damage to the pedicle from overzealous dissection.

In general, the arc of rotation is inversely proportional to the number of vascular pedicles. If a muscle has a large number of pedicles, it usually has a limited arc of rotation. Type IV muscles, such as the sartorius and tibialis anterior, are examples of muscles with multiple segmental vascular pedicles and limited arcs of rotation. Similarly, the location of the dominant vascular pedicle relative to the muscle's origin and insertion greatly determines the arc of rotation. The closer the dominant vascular pedicle is to either the origin or insertion of the muscle, the greater the arc of rotation. The point of rotation for types I, II, III, and V muscles generally are located at one end or the proximal third of the muscle. For example, type V muscles, such as the pectoralis major and latissimus dorsi, have their major vascular pedicle near their insertion, and correspondingly have a wide arc of rotation. Certain muscles, such as type V muscles, have two arcs of rotation. The first arc of rotation is based on the dominant blood supply, while the second is based on the secondary segmental vascular pedicles. Reverse arc of rotation refers to the degree of transposition of a flap based on its secondary segmental vascular pedicles.

A muscle can be split and a portion in continuity with the dominant vascular pedicle can be used as a transposition flap using just a segment of the muscle. Techniques of muscle splitting to preserve tissue and function have been described. The remaining muscle with its origin and insertion is maintained to preserve function. Alternatively, the entire muscle may be split and used to cover two defects simultaneously. Frequently, only a part of the muscle in proximity to the dominant vascular pedicle is elevated for microvascular transplantation. The skin territory may also be modified and split into two separate skin islands or elevated with only a segment of the muscle flap. However, the skin territory must include vascular connections via musculocutaneous perforating vessels from the segmental flap (Figs. 22.9 & 22.10).

The basis for splitting the pectoralis major muscle was demonstrated by Tobin in 1985.⁴³ The pectoralis has three segmental neurovascular subunits: the clavicular, the sterno-costal, and the external subunit. These can be surgically split and independently transferred on vascular pedicles from the thoracoacromial, internal mammary and lateral thoracic vessels.⁴⁴ Splitting of the pectoralis major muscle into segments has been performed when the segmental transfer of a single intercostal portion of the pectoralis muscle, based on a single medial perforating branch of the internal thoracic artery, is required for chest wall and neck reconstruction (Figs. 22.11 & 22.12).⁴⁵ The concept of segmental transposition of muscle allows transplantation of independent neuromuscular units (segments of muscle innervated by a single nerve fascicle).⁴⁶

Selection of the most appropriate reconstructive method can be difficult. Careful consideration must be given to all the possible methods of repair, and the advantages and disadvantages of each technique must be weighed accordingly.

Fig. 22.9 Gluteus maximus segmental muscle transposition. (A) Superior half of gluteus maximus, arc to sacrum. (B) Inferior half of gluteus maximus muscle.

The advantages of muscle or musculocutaneous flaps include the following:

1. The vascular pedicles are specific and reliable.
2. The vascular pedicle is often located outside the surgical defect, which can be particularly important for wounds with an extensive zone of injury beyond the actual wound (e.g., after irradiation, trauma).

Fig. 22.10 (A–E) Function-preserving muscle flap design.

3. The muscle provides bulk for deep, extensive defects and protective padding for exposed vital structures (e.g., tendons, nerves, vessels, bones, and prostheses).
4. Muscle is malleable and can be manipulated (e.g., folded on itself) to produce a desired shape or volume.
5. Well-vascularized muscle is resistant to bacterial inoculation and infection.⁴⁷
6. Reconstruction by use of muscle or musculocutaneous flaps is often a one-stage procedure.
7. Restoration of function, whether motor or sensory, is possible with certain flaps.
8. The reliability and availability of muscle and musculocutaneous flaps make them an excellent alternative means of reconstruction when the closure

Fig. 22.11 (A,B) Pectoralis major muscle flap segmental transposition.

method of choice for a particular defect is unavailable or inadequate.

The disadvantages of muscle and musculocutaneous flaps include the following:

1. The donor defect may lose some degree of function.
2. The donor defect may be aesthetically undesirable.
3. Reconstruction with muscle or musculocutaneous flaps may provide excessive bulk, leaving an aesthetically unacceptable result.

4. Muscle or musculocutaneous flaps may atrophy over time and thus fail to provide adequate coverage.
5. Removal of the muscle or musculocutaneous flap may result in contour deformities at the donor site.

The preservation of function can be extremely important when nonexpendable muscles are used as flaps. The techniques of function preservation generally involve transposing part of the muscle without completely interrupting the origin or insertion of the donor muscle. For example, the

Fig. 22.12 Tibialis anterior muscle flaps split for segmental transposition. (A) Segmental flap. (B) Posterior advancement. (C) Anterior turnover flap.

transposition of the superior half of the gluteus maximus muscle for sacral coverage in the ambulatory patient can be performed without loss of thigh extension or hip stability because the remainder of the gluteus maximus is functionally intact.^{48,49}

Fascia and fasciocutaneous flaps

A growing knowledge of the source of skin circulation after the recognition of the muscle and musculocutaneous system led to the identification of vascular pedicles emerging between muscles (septocutaneous pedicles) and entering the deep fascia. Elevation of the skin with its deep fascia represented a new vascular basis for flap design.

A fascial flap consists of fascia detached from its normal origin or insertion and transposed to another location. Without the overlying skin and fat, this represents a delicate flap. A fasciocutaneous flap, originally called an axial flap, includes the skin, subcutaneous tissue, and underlying fascia, which may be distinct from the fascia covering the underlying muscle. The vascular supply is derived at the base of the flap from musculocutaneous perforators or direct septocutaneous branches of major arteries.

The first fascia and fasciocutaneous flaps were described by Ponten in 1981 for lower extremity reconstruction and Tolhurst in 1983 for trunk and axillary reconstruction.^{23,28} Investigations have shown that the fasciocutaneous system consists of perforating vessels that arise from regional arteries and pass along the fibrous septa between muscle bellies or muscle compartments. The vessels then spread out at the level of the deep fascia, both above and below, to form plexuses, which in turn give off branches to the skin. In 1975, Schafer found three major vascular systems of the deep fascia.⁵⁰

1. Perforating arteries from underlying muscle giving off several radiating branches, which perforate the fascia before continuing to the subdermal plexus.
2. Subcutaneous arteries running in the fat and anastomosing frequently with the superficial plexus of the deep fascia and with each other.
3. Subfascial arteries arising from the intermuscular septa and running in the loose areolar tissue beneath the deep fascia and adjoining the deep and superficial plexus.

These pedicles consist of an artery (generally a branch of the artery to the specific anatomic region of the fascia and regional musculature) and paired venae comitantes that drain into corresponding major regional veins. Direct cutaneous and septocutaneous pedicles are fairly constant in location. There is a greater variability in location of the musculocutaneous perforators. These pedicles provide a vascular basis for specific fascial or fasciocutaneous flaps. On this basis, Mathes and Nahai have classified fascia and fasciocutaneous flaps as types A, B, and C (Fig. 22.13).²⁶

Anatomic studies demonstrate that type A fasciocutaneous flaps have a vascular pedicle to the deep fascia that emerges from a regional source coursing initially beneath the deep fascia and eventually continuing its course superficial to the deep fascia. This pedicle provides numerous fasciocutaneous perforators to the skin. Because the pedicle tends to course in a radial fashion from its regional source into its distal cutaneous distribution, the flap is often referred to as an axial flap. The long, relatively superficial course of the dominant

Fig. 22.13 Mathes-Nahai classification of fascia/fasciocutaneous flaps.

pedicle permits evaluation by palpation or Doppler probe (Table 22.8).

Type B fasciocutaneous flaps have a septocutaneous pedicle, which courses between major muscle groups in an intermuscular septum or between adjacent muscles. This pedicle is located within the intermuscular septum or the potential space between adjacent muscles and supplies a regional fascial vascular system. The largest septocutaneous pedicles are dominant pedicles to specific fasciocutaneous flaps and are fairly constant in location (Table 22.9).

In certain regions, larger musculocutaneous perforators enter the deep fascia and contribute to both the deep fascia and cutaneous circulation. The design of a fasciocutaneous flap can be based on these dominant perforating vessels without incorporation of the underlying muscle; this vascular pattern represents the type C fasciocutaneous flap. However, increasing pedicle length will necessitate proximal dissection of the pedicle through muscle to its regional source or incorporation of all or part of the muscle in the flap design. Type

C flaps are generally the anatomic model used for the perforator flap in microsurgical transplantation (Table 22.10).

Cormack and Lamberty also classified fasciocutaneous flaps based on vascular anatomy.^{29,40} The type A flap is supplied by multiple fasciocutaneous perforators that enter at the base of the flap and extend throughout the longitudinal length. The flap can be based proximally, distally, or as an island. The type B flap has a single fasciocutaneous perforator, which is of moderate size and is fairly consistent. It is intended for use as a free flap. The type C flap is based on multiple small perforators that run along a fascial septum.

The supplying artery is included within the flap. It may be based proximally, distally, or as a free flap. The type D flap is an osteomusculofasciocutaneous flap, and is based on multiple small perforators similar to the type C flap, but also includes a portion of adjacent muscle and bone. It may be based proximally or distally on a pedicle or used for microvascular tissue transplantation (Fig. 22.14).

Nakajima *et al.* expanded the types of fasciocutaneous flaps and described them originating from 6 different types of perforators piercing the deep fascia feeding to the plexus of the skin (Fig. 22.15).³⁷ Type A, direct cutaneous branch of muscular vessel was described in the same manner as axial pattern flaps of McGregor and Morgan.⁵¹ Type B, septocutaneous perforator was the same as type B from the classification of Cormack and Lamberty.⁴⁰ Type C, direct cutaneous branch and type D, musculocutaneous perforator supplying the fasciocutaneous flap were not quite described in previous classifications. These types, especially type D from the Nakajima *et al.* classification, further play a pivotal role for setting up the concept of true perforator flaps.⁵² Type E, direct septocutaneous describes type C from the classification of Cormack and Lamberty and type F, perforating cutaneous branch of muscular vessel resembles traditional musculocutaneous flaps.^{22,29,40}

The fasciocutaneous flap is used as a local flap, the standard arc of rotation is determined by the extent of elevation of the deep fascia from its normal anatomic position to reach adjacent defects. The point of rotation is based on the site of entrance of the dominant vascular pedicle into the fascia. The fascia or fasciocutaneous flap is elevated to the point of entrance of the flap pedicle, and the fascia and overlying skin distal to this point are rotated into the defect.

The advantages and disadvantages of these flaps are somewhat similar to those of muscle flaps, although there are a few exceptions. The advantages include the following:

1. They are thin and pliable.
2. The blood supply is reliable and robust.
3. The donor site morbidity is minimal in regard to function.
4. They are muscle sparing.
5. They have the ability to restore sensation.
6. There are many potential donor sites.

The disadvantages of fascia, fasciocutaneous, and perforator flaps include the following:

1. There is a lack of bulk for deep defects.
2. They are technically more challenging (pedicle dissection; many require microvascular anastomosis or at least microvascular techniques).
3. There are size limitations.
4. The arc of rotation is sometimes limited though often better than the similar muscle flap because of the longer pedicle.
5. Donor site may require skin graft closure, resulting in donor site deformity.

Perforator flap (skin with fat and with or without fascia)

Further refinements in flap application have led to the development of perforator flaps. Perforator flaps have evolved

from musculocutaneous and fasciocutaneous flaps without the muscle or fascial carrier. It was a natural evolution as reconstruction needed fine-tuning while aiming to minimize donor morbidities. A good example of this evolution would be the change from transverse rectus abdominis muscle (TRAM) flaps to muscle-sparing TRAM to deep inferior epigastric perforator (DIEP) flaps (Fig. 22.16). Transformation of these flaps has shown that neither a passive muscle carrier nor the underlying fascial plexus of vessels are necessary for flap survival.⁵³ Thus, a perforator flap is a skin flap (with or without fascia) based on a single perforator.⁵⁴ Like the angiosome concept showing the vascular territory of a source vessel, one must understand the anatomy and physiology of a single perforator territory to obtain the ideal design of the perforator flap.³³ The perforasome theory by Saint-Cyr reported four major characteristics of a perforator flap: (1) each perforasome is linked with adjacent perforasomes by means of direct and indirect linking vessels (Fig. 22.17); (2) flap design and skin paddle orientation should be based on the direction of the linking vessels, which is axial in the extremities and perpendicular to the midline in the trunk (Fig. 22.18); (3) filling of the perforasomes occurs within perforasomes of the same source artery first followed by perforators of the other adjacent source arteries; (4) mass vascularity of a perforator found adjacent to an articulation is directed away from that same articulation (Fig. 22.19).³⁸ This theory provides insights into perforator flap vascularity and can clinically guide to the harvest of a safer free or pedicle perforator flap.

In 1989 Koshima and Soeda used the term “perforator flaps” in their harvest for paraumbilical skin and fat island flaps based on a muscular perforator.⁵³ Since then, perforator-based flaps using lower abdomen skin flaps have been applied for breast reconstruction.^{55,56} Slowly other perforator-based flaps have been introduced from various parts of the skin.

The nomenclature of perforator flaps is confusing and oftentimes misstated. Perforator flaps have been designated by their location (e.g., anterolateral thigh flap), arterial supply (e.g., deep inferior epigastric artery perforator flap), or the muscle of origin (e.g., gastrocnemius perforator flap). Thus, a

clear definition and classification for perforator flaps was needed. Hallock defines a perforator as any vessel that pierces through the fenestration in the deep fascia regardless of origin.⁵⁴ In a consensus document for perforator flap terminology, perforators that pierce through the deep fascia without traversing any other structural tissues were called direct perforators while indirect perforators run through deeper

Fig. 22.15 The six distinctive deep fascia perforators according to Nakajima and colleagues are indicated. A, direct cutaneous branch of a muscular vessel; B, septocutaneous perforator; C, direct cutaneous; D, musculocutaneous perforator; E, direct septocutaneous; F, perforating cutaneous branch of a muscular vessel. A separate type of fasciocutaneous flap could be named after each different perforator. (Modified from Nakajima H, Fujino T, Adachi S. A new concept of vascular supply to the skin and classification of skin flaps according to their vascularization. *Ann Plast Surg.* 1986;16:1–19.)

Fig. 22.16 Evolution of the abdominal skin flap for breast reconstruction from transverse rectus abdominis muscle (TRAM) flap (A) to muscle-sparing TRAM (B) to deep inferior epigastric perforator (DIEP) flaps (C).

structures such as muscles, septum and perimysium.^{54,57} Evolved from the six patterns of fascial perforators of Nakajima *et al.*, the consensus paper simplified it into 5 types of perforator based on the surgical approach for dissection of the perforators (**Fig. 22.20**). Type 1: direct perforators perforate the deep fascia only; type 2: indirect muscle perforators

predominantly supply the subcutaneous tissues; type 3: indirect muscle perforators predominantly supply the muscle but have secondary branches to the subcutaneous tissues; type 4: indirect perimysial perforators travel within the perimysium between muscle fiber before piercing the deep fascia; type 5: indirect septal perforators travel through the

Fig. 22.18 Orientation of the perforators should be understood and utilized when designing flaps. The skin paddle orientation should be based on the direction of the linking vessels, which is axial in the extremities and perpendicular to the midline in the trunk.

Fig. 22.19 Direction of perforator flow between articulations.

intermuscular septum before piercing the deep fascia. Based on this distinction of different perforators, the consensus paper gives definitions and classification for perforator flaps as follows:

Definition 1: A perforator flap is a flap consisting of skin and/or subcutaneous fat. The vessels that supply the blood to the flap are isolated perforator(s). These perforators may pass either through or in between deep tissues (mostly muscle).

Definition 2: A muscle perforator is a blood vessel that traverses through septum to supply the overlying skin.

Definition 3: A septal perforator is a blood vessel that traverses only through septum to supply the overlying skin.

Definition 4: A flap that is vascularized by a muscle perforator is called a muscle perforator flap.

Definition 5: A flap vascularized by a septal perforator is called a septal perforator flap.

Definition 6: A perforator flap should be named after the nutrient artery or vessels and not after the underlying muscle. If there is a potential to harvest multiple perforator flaps from one vessel, the name of each flap should be based on its anatomical region or muscle.

This terminology and the classification into indirect and direct perforator flaps and further into septal and muscle perforator flaps were set up to clearly identify the course of these small terminal branches before they pierce the deep fascia and the technical implications during the surgical procedure.^{57,58} Table 22.11 shows some of the popular perforator flaps based on this terminology. Recent innovations in this field have made some of the terminology and classification somewhat misleading. As with all evolution, new classification and terminology will be constantly updated.

The perforator flap concept simplified and overcame the applications and limits of classic local flaps. By identifying the perforator as the pedicle and further dissecting toward the source vessel, it allowed improved movement and better survival of flap. One form of perforator-based local flap, the propeller flap, is an island flap that reaches the recipient site through an axial rotation.^{59,60} When a perforator propeller flap is being elevated, the perforator is dissected free from the fascial and fat adhesions to minimize the chance of kinking. Although less rotation reduces the chance for kinking, the skin island may be safely rotated up to 180° (Fig. 22.21).

Advantages of perforator flaps include:

1. Reduced donor site morbidity
2. Versatility in flap design
3. Muscle sparing (less functional deficit)
4. Improved postoperative recovery of the patient.^{61–65}

Disadvantages of perforator flaps may include:

1. Meticulous dissection needed to isolate the perforator vessels
2. Increased operative time especially in muscle perforators
3. The variability in the position and size of the perforator vessels
4. Steep learning curve.^{66,67}

However, modifications such as the free-style approach and supermicrosurgery have further simplified the approach and increased the use of perforator flaps.^{68–70} The free-style

Fig. 22.20 The different types of direct and indirect perforator vessels with regard to their surgical importance. 1, Direct perforators perforate the deep fascia only; 2, indirect muscle perforators predominantly supply the subcutaneous tissues; 3, indirect muscle perforators predominantly supply the muscle but have secondary branches to the subcutaneous tissues; 4, indirect perimysial perforators travel within the perimysium between muscle fibers before piercing the deep fascia; 5, indirect septal perforators travel through the intermuscular septum before piercing the deep fascia. (Adapted from Blondeel PN, Van Landuyt KH, Monstrey SJ, et al. The "Gent" consensus on perforator flap terminology: preliminary definitions. *Plast Reconstr Surg*. 2003;112:1378–1383; quiz 1383, 1516; discussion 1384–1387.)

Table 22.11 Perforator flap terminology

Flap – abbreviation	Flap – full name	Nutrient artery
Muscle perforator flaps		
DIEP	Deep inferior epigastric perforator	Deep inferior epigastric vessels
TAP	Thoracodorsal artery perforator	Thoracodorsal vessels
SGAP	Superior gluteal artery perforator	Superior gluteal vessels
IGAP	Inferior gluteal artery perforator	Inferior gluteal vessels
IMAP	Internal mammary artery perforator	Internal mammary vessels
ICAP	Intercostal perforator	Intercostal vessels
PLP	Paralumbal perforator	Paralumbal perforating vessels
GP	Gracilis perforator	Medial circumflex femoris vessels
TFLP	Tensor fasciae latae perforator	Transverse branch of the lateral circumflex femoris vessels
ALTP	Anterolateral thigh perforator	Descending branch of the lateral circumflex femoris vessels
AMTP	Anteromedial thigh perforator	Innominate branch of the descending branch of the lateral circumflex femoris vessels
SAP	Sural artery perforator	Sural vessels
PTAP	Posterior tibial artery perforator	Posterior tibial vessels
ATAP	Anterior tibial artery perforator	Anterior tibial vessels
Septal perforator flaps		
RAP	Radial artery perforator	Radial vessels
AP	Adductor perforator	Medial circumflex femoris vessels
AMTP	Anteromedial thigh perforator	Innominate branch of the descending branch of the lateral circumflex femoris vessels (if perforator runs only in septum)
ALTP	Anterolateral thigh perforator	Descending branch of the circumflex femoris lateralis vessels (if perforator runs only in the septum)

(From Blondeel PN, Van Landuyt KH, Monstrey SJ, et al. The “Gent” consensus on perforator flap terminology: preliminary definitions. *Plast Reconstr Surg*. 2003;112:1378–1383; quiz 1383, 1516; discussion 1384–1387.)

approach identifies the perforator feeding the skin flap first and then dissects proximally toward the source vessel contrary to the classic approach where identification of the source vessel was made first and then dissection toward the perforator. This allows the freedom to design flaps based on any perforator as well as alleviate the risk for pedicle variation.⁶⁸ The supermicrosurgery approach, perforator to perforator anastomosis, allows harvesting the flap as a short pedicled flap, reducing the dissection time and minimizing the risk for traumatizing the pedicle during dissection.^{69,71}

Visceral flaps

The abdominal viscera are not easily classified; however, for the purposes of flap transposition or microvascular tissue transplantation, the colon, jejunum, and omentum fall conveniently into the muscle classification system (Table 22.12). For microvascular transplantation, the segment of bowel (jejunum or colon) is elevated on one vascular arcade with a single dominant vessel, a type I pattern of circulation. In unusual circumstances where a longer segment of bowel extends beyond the vascular territory of one arcade, two vascular arcades must be included to ensure viability of this longer segment of bowel. In this instance, the pattern of circulation will be type III (two dominant arcades or pedicles). It is possible to reconstruct the esophagus from the base of the tongue

to the stomach with a long segment of jejunum where one pedicle is revascularized in the upper chest or neck and the second pedicle is left intact. Additional uses of the colon or jejunum as flaps have been for vaginal reconstruction. The appendix, as a type I pattern based on the appendiceal artery and vein, has been used for reconstructing the urethra and for voice reconstruction.^{72–74}

Table 22.12 Abdominal visceral flap classification

Flap	Type	Circulation pattern	Size
Colon	Bowel	Type I	20–25 cm in length Lumen diameter of 8 cm
Jejunum	Bowel	Type I	7–25 cm may be transferred on one pedicle Lumen diameter of 3–5 cm
Omentum	Omentum	Type III	Variable; up to 40×60 cm

The omentum may be based as a transposition flap on either the right or left gastroepiploic vessels and is thus classified as having a type III pattern of circulation. The omentum is also commonly transferred microsurgically. The omentum can be used to reconstruct a wide range of extraperitoneal defects and has been shown to have immunologic and angiogenic properties.⁷⁵⁻⁷⁷ Although useful for reconstruction, donor site complications can be significant, including abdominal wall infection and hernia.^{78,79} With the advances in minimally invasive surgery, the abdominal viscera can successfully be harvested laparoscopically obviating the need for a large midline incision providing a better cosmetic result and less donor site morbidity.^{31,80,81}

Fig. 22.21 One form of perforator-based local flap, the propeller flap, is an island flap that reaches the recipient site through an axial rotation.

Bone flap (vascularized bone, osseous–periosteal flap)

Bone is vascularized through endosteal and periosteal sources (Fig. 22.22). The complex blood supply of bone is based on nutrient vessels entering the bone directly and through vascular connections between muscles and bone, typically where the muscle has a large bony origin or insertion. Vascularized bone is useful in muscles suitable for microvascular transplantation or in those muscles designed for transposition when the vascular attachments to bone are distal to the point of rotation. The commonly transferred bones include the fibula based on the peroneal artery, iliac crest based on the deep circumflex iliac artery (Fig. 22.23), the scapula based on the circumflex scapula or thoracodorsal arteries (Fig. 22.24), and the radius based on the radial artery (Fig. 22.25). The calvarial osseous flap based on the superficial temporal artery or occipital artery with partial- or full-thickness bone is also useful for reconstructing facial anomalies and deformities (Fig. 22.26).⁸²⁻⁸⁵

The use of periosteum and part of the cortical bone as an osseous–periosteal flap is being widely used for nonunion of the bone and small bone defects. The genicular osseous–periosteal flap, also known as the medial femoral condyle flap, based on the articular branch of the descending genicular artery and vein with periosteum and a thin (0.5 to 1.0 mm) layer of outer cortical bone, was first reported by Sakai *et al.* to treat fracture nonunion (Fig. 22.27).⁸⁶ Further applications of this flap with or without skin and cartilage expanded to reconstructing small bone defects, avascular necrosis of the bone and other complex defects of the hand.⁸⁷⁻⁸⁹

There is no widely accepted classification of bone flaps alone. Perhaps it is due to the complexity of the vasculature to each bone. One of the most widely used, the fibula, has vascular supply from the branches of the anterior tibial artery supplying the head, neck, and epiphysis while the peroneal

artery gives rise to multiple arcuate vessels along the fibula and a nutrient vessel in the mid third of the fibula bone (Fig. 22.28). Thus, depending on the portion of the fibula bone being harvested, the pedicle of the bone flap can differ not only in anatomical region but also in type of vascular supply to the bone. The fibula bone flap with or without the skin (fasciocutaneous) flap is frequently used for segmental bone defects especially after mandibular resection, long bone resection and for pelvis reconstruction (see Fig. 22.23).⁹⁰ The fibular bone including the head and epiphyseal growth plate is used in patients who need further growth of the long bone such as reconstruction after sarcoma resection of the proximal humerus.^{91,92}

Nerve flap

The sensory nerves are supplied by an extrinsic and intrinsic blood supply. The extrinsic blood supply to the peripheral nerves consists of arteriae nervorum that rise directly from the perforating vessels. These perforating vessels may originate from various deeper vessels as seen from Nakajima's perforator classification.³⁷ These small arteriae nervorum enter the nerve and terminate intraneurally. The intrinsic blood supplies are the longitudinally oriented arterioles located on the epineurium, perineurium, and endoneurium. The intrinsic vessels communicate and receive vascular supply from the extrinsic arteriae nervorum and the end branches (Fig. 22.29).^{93,94} Thus, the nerve flap can be harvested from superficially located sensory nerves based on perforating vessels originating from a proximal source vessel. Based on this clear distinction of tissue being supplied by a vascular source, the term "vascularized nerve graft" would be a misnomer and "nerve flap" should be used to minimize confusion. Currently there is no classification for nerve flaps.

Well-known examples of nerve flaps would be superficial radial nerve flap based on the radial artery and accompanying veins, saphenous nerve flap proximally based on the branches

Fig. 22.25 An osteocutaneous flap with composition of radius bone, and attached fasciocutaneous flap is elevated based on the proximal radial artery and vein pedicle.

from the femoral artery and distally based on the saphenous artery, and sural nerve flap based on the superficial sural artery or medial sural artery.⁹⁵⁻⁹⁹

In cases where perforators are not found leading to the superficial nerve, one can use the accompanying vein along the superficial nerve in an arterialized fashion. A typical example would be the sural nerve flap, where an arterial supply such as superficial sural artery, medial or lateral sural artery would be missing and the lesser saphenous vein would be arterialized (Fig. 22.30).¹⁰⁰⁻¹⁰²

Lymph node flap

Each lymph node has afferent lymphatic vessels that transport lymph to the node and an efferent vessel that transports fluid toward the thorax and into the chylothoracic duct. The node itself also has its vascular supply based on arterial inflow and

Fig. 22.26 The calvarial osseous flap based on the superficial temporal artery with a segment of temporal fascia and muscle is elevated.

venous outflow (Fig. 22.31). This is why lymph node(s) with fat can be considered as a flap. It is this lymph node flap transfer that offers a solution to lymphedema patients. Often lymph node vessels are extremely small and may require supermicrosurgery technique to anastomose to a recipient vessel but can be anastomosed comfortably when dissected proximally toward the source vessels such as superficial inferior epigastric artery, superficial circumflex iliac artery, and supraclavicular artery.^{103–106} Although the mechanism remains unclear, clinical reports have been encouraging along with lymphovenous shunting for lymphedema.^{106,107}

Flaps based on construction (flow)

For most of the flaps, whether they be muscle or skin or a combination of various tissues, the pedicle usually drains into a single source making unipedicle the most common form. We do not use the term unipedicle as part of the nomenclature but as a default to communicate. The same can be said for antegrade (orthograde) flow. A bipedicle flap is a flap with dual pedicle, often used as a random pattern skin flap to cover a defect on the extremity, or a transabdominal bipedicle flap

can be raised to provide coverage on the dorsum of the hand (Fig. 22.32).

Retrograde-flow flaps

A flap based on the antegrade flow has a major pedicle that flows with the flap but, when the same flap has its orthograde pedicle ligated proximally, becomes a flap based on the distal part of the major pedicle and the flow of the flap becomes reversed (Fig. 22.33A). This concept was first reported by Bostwick *et al.* using a reverse-flow temporal artery island flap.¹⁰⁸ In reality, some of the random pattern flaps or axial cutaneous flaps were used in a reverse manner without realizing the axi-ality and direction of the flow, such as acromio-thoracic tube pedicle.¹⁰⁹

A number of clinically useful retrograde (reverse) flow flaps have been described since its original description in 1976, including the distally based radial forearm fasciocutaneous flap, posterior interosseous flap, and the reversed first dorsal metacarpal artery flap used in hand reconstruction.^{110–112} The distally based radial forearm flap relies on retrograde flow through the deep palmar arch and associated venae

Fig. 22.27 The genicular osseous-periosteal flap, also known as the medial femoral condyle flap, is based on the articular branch of the descending genicular artery and vein with periosteum and thin (0.5–1.0 mm) layer of outer cortical bone (A). It is commonly used to reconstruct small bone defects, avascular necrosis of the bone and other complex defects of the hand (B). MCL, medial collateral ligament.

comitantes with the rotation point of the reverse flap at the level of the wrist (Fig. 22.33B). Examples of reversed flow flaps used for lower extremity reconstruction are sural fasciocutaneous flaps based on perforators from the peroneal artery, lateral calcaneal flaps based on reverse flow of the lateral calcaneal artery and reversed flexor hallucis longus flaps based on retrograde flow through the peroneal artery.^{113–115}

The reverse-flow island sural flap is based on the superficial sural artery. The anatomic structures in the path of the pedicle are superficial and deep fascia, the sural nerve, the short saphenous vein, and the superficial sural artery. The sural nerve usually descends between the two heads of the gastrocnemius muscle and penetrates the deep fascia at the mid leg. The median branch of the superficial sural artery follows the course of the sural nerve and descends to the ankle region anastomosing with the peroneal artery. Thus, when the sural artery and nerve is ligated proximally and the flap is distally positioned, the flap has a reverse flow from the peroneal artery (Fig. 22.34).^{113,116} There are some disadvantages for reverse-flow island flaps regarding venous drainage despite the connections between accompanying veins, and they may

result in venous congestion. Patients with venous insufficiency and increasing age were identified as risk factors for flap complications.¹¹⁷ Other concerns can be the poor cosmetics of the donor site as it has to be grafted for larger flaps and hypoesthesia of the lateral aspect of the foot. Nevertheless, it can provide excellent coverage for heel, ankle and the dorsum of the foot when microsurgery is not feasible.

Turbocharged and supercharged flap

This term was based on the observation of automotive terms by Semple.¹¹⁸ “Supercharging” is using an external power source to boost the engine’s performance. Thus, in addition to its original vascular source, using an unrelated distant vascular source to anastomose to a flap may result in augmentation of either inflow or outflow. An example would be the superior unipedicled transverse rectus abdominis musculocutaneous (TRAM) flap salvaged by an anastomosis of a thoracic or upper extremity vascular source to the contralateral deep or superficial inferior epigastric vessels.^{42,119,120} “Turbocharging” is using the engine exhaust for additional power. Thus, using

Fig. 22.28 One of the most widely used bones, the fibula, has vascular supply from the peroneal artery, giving rise to multiple arcuate vessels along the fibula and a nutrient vessel in the mid third of the fibula bone (A). The branches of the anterior tibial artery supply the head, neck, and epiphysis and this part of the fibula bone can be used as an osseous flap to reconstruct the defect after proximal humerus resection in a growing child (B).

Fig. 22.29 The extrinsic blood supply to the peripheral nerves consists of arteriae nervorum that rise directly from the perforating vessels (A). These small arteriae nervorum enter the nerve and terminate intraneurally. The intrinsic blood supplies are the longitudinally oriented arterioles located on the epineurium, perineurium, and endoneurium (B). Thus, the nerve flap can be harvested from superficially located sensory nerves based on perforating vessels originating from a proximal source vessel.

Fig. 22.30 The sural nerve flap, where an arterial supply such as the superficial sural artery, medial or lateral sural artery would be missing and the lesser saphenous vein would be arterialized.

the main vascular source to connect to an additional pedicle from the same flap creates a direct flow to the vascular territory of the connected branch. An example would be directly connecting the ipsilateral and contralateral deep inferior epigastric vessels of a TRAM flap to improve the vascular supply to the whole TRAM flap (Fig. 22.35).^{42,118,121}

Venous flaps (arterialized venous flap)

A venous flap is defined as a composite flap of skin, subcutaneous tissue and other tissues such as nerve, tendon, and bone that uses a subcutaneous vein for the arterial inflow and venous outflow. Nakayama *et al.* first described these flaps in 1981.¹²² Arterialized venous flaps differ from conventional flaps in that the arterial inflow–capillaries–venous outflow is replaced by the arterial inflow–without capillary network–venous outflow. The flap does not require a donor site artery; the flap can be harvested very thinly based on the superficial veins, and can be harvested rapidly. It is widely

Fig. 22.31 Lymph node vascular supply, based on arterial inflow and venous outflow, should be elevated with the surrounding fat tissue.

Fig. 22.32 A bipedicle flap is a flap with dual pedicle often used as a random pattern skin flap to cover the defect on the extremity or transabdominal bipedicle flap.

used for soft tissue repair on the hands and fingers when local flaps and other conventional flaps are not readily available.^{123–125} There are considerable controversies on the mechanism of flap survival but three main theories have been postulated: (1) A–V shunting: retrograde flow from the venous system to the arterial system via paralyzed arterial–venous shunts; (2) reverse flow: flow from the venules into the capillaries; (3) capillary bypass: flow through the venous system without entrance into the arterial side until neovascularization.¹²⁶

Fig. 22.33 A flap based on the antegrade flow has a major pedicle that flows with the flap (A) but when the same flap has its orthograde pedicle ligated proximally, it becomes a flap based on the distal part of the major pedicle and the flow of the flap becomes reversed (B).

Fig. 22.34 The reverse sural flap is elevated by ligating the sural artery and nerve proximally (A) and distally positioning the flap resulting in a reverse flow from the peroneal artery (B). The arc of rotation allows the flap to reach the heel but skin graft is usually needed to cover the donor site.

Fig. 22.35 Supercharging is using an external power source to boost the engine's performance (A). Turbocharging is using the engine's exhaust for additional power, like using the same main vascular source to connect to an additional pedicle from the same flap (B).

Based on the earlier classification by Thatte and then by Chen, in 2007, Woo *et al.* refined the classification of arterialized venous flaps used in hand and finger reconstruction into three types.^{125,127,128} Woo's classification is based on the presence of an intravenous valve, the venous network of the donor site, the location, and the number of veins at the recipient site. Type I is a "through-and-along-valve" type which mimics similar blood flow as in a standard vein graft with a straight or Y-shaped pattern. Type II is against-valve, which is arterial inflow against the valve through the afferent vein with a reversed Y- or H-shaped venous network. In type III venous flaps, venous flow drains through efferent veins against intravenous valves (Fig. 22.36).

These flaps have had success in hand reconstruction. The availability of small, thin flaps with defined arterial inflow and venous outflow is limited. Thus, when local flaps are not available, arterialized venous free flaps provide a good solution for successful soft tissue reconstruction (Fig. 22.37).

Flaps based on conditioning

Delay

The delay procedure was naturally developed to overcome the limitations of random pattern flaps. Given the vascular limitations of the random pattern flap, investigators attempted different means by which to maximize the potential area of a flap, which led to the concept of flap delay. Although the delay procedure has been used for several hundred years, it was not until the early 1900s that the concept was recognized. Blair introduced the term "delayed transfer" in 1921.⁸¹ In the 16th century Tagliacozzi delayed his upper arm flaps by making parallel incisions through the skin and subcutaneous tissue overlying the biceps muscle. In 1965, using the pig

Fig. 22.36 The venous flap classification. Type I is a "through-and-along-valve" type which mimics similar blood flow as in a standard vein graft with a straight or Y-shaped pattern. Type II is against-valve, which is arterial inflow against the valve through the afferent vein with a reversed Y- or H- shaped venous network. In type III venous flaps, venous flow drains through efferent veins against intravenous valves.

model, Milton investigated the effectiveness of four different methods of delaying a flap. He found that in developing a bipedicle flap, the best form of delay was by making two incisions and undermining the skin between the incisions.³¹ The goal of a delayed flap is to enhance flap circulation, ensuring flap survival after advancement, transposition, or transplantation to a defect site. Flap delay may be used to increase circulation to the muscle or fascia or to enhance vascular connections to the overlying cutaneous territory or adjacent structures to be included during flap elevations (tendon, fascia, and bone). Although delay may be accomplished by biochemical means to improve flap perfusion, currently the most effective method to ensure delay is surgical manipulation of the flap. To date, no pharmacologic method has surpassed the reproducibility and the degree to which surgical delay protects against flap necrosis.⁷⁷ There are two theories that describe the potential mechanism by which the delay phenomenon prevents skin necrosis. The first is that delay acclimatizes the flap to ischemia (tolerance), permitting it to survive with less blood flow than would normally be required. This theory suggests that vascular delay causes adaptive metabolic changes at a cellular level within the tissue.⁹⁶ The second theory is that delay improves vascularity by increasing flow through pre-existing vessels, reorganizing the pattern of blood flow to more ischemic areas.^{103,104} On the basis of experimental data, it appears that both of these mechanisms, either directly or indirectly, contribute to the beneficial effects of surgical delay. Regardless of the underlying mechanisms, most experimental work on surgical delay demonstrates changes at the microcirculatory level.^{129,130}

Surgical flap delay is accomplished in two ways: standard delay, with an incision at the periphery of the cutaneous territory or partial flap elevation; and strategic delay, with division of selected pedicles to the flap to enhance perfusion through the remaining pedicle or pedicles.

The technical aspects of standard surgical delay to enhance circulation are straightforward. The flap cutaneous territory is outlined and incisions are made through all or part of the border of a planned cutaneous territory (Fig. 22.38). Minimal to partial flap undermining is performed. The incisions are then closed. The flap is then elevated after 10–14 days. It has been shown that after 1 week, the blood flow into the area of delay reaches a maximum.¹³¹

Fig. 22.38 Standard delay flap modification. (A) Cutaneous territory of flap. (B) Delay incision. (C) Delay incision with partial distal flap elevation.

Strategic pedicle delay is accomplished by making incisions at the border of the planned flap cutaneous territory. The dissection is either deep to muscle or fascia, depending on the flap type, to reach pedicles entering the flap territory. These pedicles are divided and the incision is closed. Second-stage flap elevation is performed after a 2-week period. Effectiveness of strategic delay based on ligation of the dominant vascular pedicle was initially demonstrated in the converse model of the gracilis musculocutaneous flap.²² This type of delay is usually advocated in patients with risk factors for flap ischemia (i.e., smoking history, obesity, radiation therapy, abdominal scar). New techniques for strategic delay are designed to minimize incision length and procedure-related morbidity. Endoscopic techniques allow access and division of pedicles with minimal incisions. Interventional radiology techniques may also be used to occlude dominant or secondary pedicles to the flap territory to enhance perfusion to the remaining flap pedicles.

Although important historically, the delay technique is used less frequently because of the development of better techniques, including axial, musculocutaneous, fasciocutaneous, transposition, perforator and microvascular free flaps. As with the random-pattern flap, the limitation of the delayed flap is that a parallel blood supply is not efficient. Flap delay also has disadvantages: a preliminary operation is required; inadvertent injury to the desired pedicle for flap design is possible; and resultant scar tissue at the site of flap delay may impair subsequent manipulation and inset of the flap at the recipient site.

The delay phenomenon may result in part from a sympathetic state that results from cutting the sympathetic innervation to the vasculature and the subsequent vasodilatation. Drugs that block vasoconstriction or those that vasodilate may be of theoretic value. Attempts have been made to stimulate the delay phenomenon pharmacologically by manipulating the autonomic nervous system.¹³² Although pharmacologic delay is of theoretical importance, additional studies need to be done to prove its effectiveness.

Tissue expansion

Skin and soft tissue adjacent to the defect are preferred for the closure of the defect because of the similarity in skin color, texture, and contour. Design of local advancement flaps will frequently allow use of adjacent tissue, particularly if there is skin excess in the donor area. A rotation or advancement flap frequently requires either a back-cut or skin graft at the donor site. The size of the defect or the surrounding zone of injury often prevents the use of adjacent tissue, which is frequently not available for wound closure or composite defect reconstruction. In these circumstances, tissue expansion may allow the use of the desired adjacent tissue for reconstruction. Tissue expansion is an effective method to enlarge the cutaneous territory of superficially located muscle and fascial flaps. Although it is most commonly used to increase the cutaneous flap territory, the principle of tissue expansion may also be applied to all soft tissues, including fascia and peripheral nerve. Neumann is credited with the first modern report of this technique in 1957.¹³³ Radovan further described the use of this technique for breast reconstruction in 1976.¹³⁴

Technically, the tissue expander is inserted under the skin to provide a mechanism for increasing skin dimensions to provide sufficient skin circumference for designing an

advancement or transposition flap. If a fasciocutaneous flap is planned, the expander is placed below the deep fascia. If a musculocutaneous flap is planned, the expander is placed beneath the deep surface of the muscle. The expander should not be placed directly beneath the dominant vascular pedicle at its point of entrance into the flap territory to avoid injury to the pedicle during the expansion process. Although immediate skin expansion is possible, delayed expansion is usually performed prior to flap elevation. During a selected time interval, usually 6 weeks to 3 months, the expander is injected with saline at weekly intervals. Once the desired amount of expansion has been achieved, the expander is removed and the modified flap skin territory is recruited for reconstruction.

Safe tissue expansion depends on surgical judgment regarding its usefulness for a specific problem. The benefits of local surrounding tissues in reconstructive surgery are well recognized; however, this tissue is frequently injured because of its proximity to the traumatic or surgical defect obviating the ability to use this tissue. Failure of tissue expansion is usually attributable to inadequate stability of skin and associated soft tissue during the expansion process. Failure of the expander is signaled by wound dehiscence followed by expander exposure and infection. Unlike failure of flap transposition or transplantation techniques, expander failure is not generally associated with increased wound complexity or donor site problems.^{36,135}

Prelaminated and prefabricated flaps

Flap prelamination, a term coined in 1994, involves surgical manipulation of a flap that requires partial to complete flap elevation and suturing of the flap to form structures at the site of the reconstruction.¹³⁶ This technique may also incorporate new tissues into the flap territory, establishing a multilayered flap. When these structures at the donor site have healed, flap transposition or transplantation is performed. With suture lines or various grafts healed at the time of flap inset, complex reconstructions are theoretically accomplished with less risk of complications at the recipient site. This is commonly done in flaps to be used in head and neck reconstruction. Baudet *et al.* and Pribaz *et al.* have used prelamination techniques on the forearm for nasal and central face reconstruction.^{32,137} Although it is useful, many reconstructive surgeons still prefer to perform secondary procedures after successful initial flap inset rather than flap prelamination at the donor site.

Another form of flap manipulation is termed prefabrication. Prefabrication provides a new dominant vascular pedicle to structures for subsequent transposition or transplantation. A suitable artery and vein are selected and buried in fascia or subcutaneous tissue in the planned flap territory. A large pedicle to an adjacent muscle is frequently used. The pedicle and a small segment of muscle are elevated and inset beneath the proposed flap site. In 6 weeks, the flap based on the new vascular pedicle is elevated and either transposed or transplanted by microsurgery. This technique for prefabrication is not always reliable for establishing a new dominant pedicle to a flap territory. With the numerous options available for safe flap selection, this technique of flap prefabrication is rarely used.¹³⁸

Sensory flap

Specific sensory nerves are identified in the cutaneous territory of many of the flaps available for reconstructive surgery.

All flaps using the skin component may be designed to incorporate the sensory nerve in the flap base. If the cutaneous nerve does not enter the flap base in proximity to the vascular pedicle, it is also possible to divide the sensory nerve during flap elevation and then subsequently coapt the nerve to a suitable sensory nerve at the recipient site.

Muscle flaps with intact motor nerves or with re-anastomosis of the motor nerve to suitable motor or sensory nerves at the recipient site appear to retain protective sensibility, possibly through nerve fibers of proprioception. Maintenance of protective sensation is essential for hands, feet and other weight-bearing areas. Another common area in which sensate flaps are used is the oral cavity and this potentially improves postoperative intraoral function.^{139–141} Harris *et al.* state that reconstruction of weight-bearing areas should provide adequate contour for normal footwear, thick durable skin, protective sensation, and solid anchorage to the deep structures to resist shearing forces.¹⁴² Studies have shown benefits of protective sensation for ankle and heel reconstruction both with rotational flaps and by microvascular tissue transfer.^{110,143,144} Sensory reinnervation for free flaps showed faster sensory recovery and flaps without sensory reinnervation did recover protective sensation but never two-point discrimination.^{144,145}

Functional muscle flaps

Release of the origin or insertion of the muscle transposition flap will result in loss of muscle function. However, many of the muscle flaps may be designed for both coverage and functional muscle transfer. For function to be preserved, the motor nerve must be preserved along with dominant vascular supply, the muscle must be reattached to a new bone or tendon across a joint, and the muscle must exert a direct force on its new point of attachment. Muscles suitable for use as transposition flaps or microvascular composite tissue transplantation, providing both coverage and function, include the latissimus, gluteus maximus (segmental), gracilis, gastrocnemius and serratus muscles. Restoration of the original muscle length-to-width ratio and repair of the motor nerve to a suitable receptor motor nerve at the recipient site are essential for restoration of transplanted muscle function at its new inset site.

Flaps based on conformation

In the era of random pattern flaps, the issues related were regardless of circulation and focused on shapes and the methods to transport flaps to distant regions. Nowadays with complex defects, multiple tissues are used to obtain an ideal reconstruction. The conformation of the flap frequently combines multiple flaps. A compound flap typically consists of multiple tissue components linked together in a manner that allows their simultaneous transfer and consequently more efficient reconstruction.^{39,41,42} Hallock's classification of compound flaps has been simplified to enhance communication and further advance the role of complex flaps, not only microsurgical but local flaps as well (Table 22.13).^{41,42} The compound flap can be partitioned into two major classes according to their primary means of vascularization (Fig. 22.39). First are the "solitary compound flaps" which are composite flaps based on solitary circulation. It is the simplest form of compound flap that contains en bloc multiple

Table 22.13 Classification of compound flaps

tissue components.²⁹ The components are dependent on each other and must remain intact together supplied by a solitary source.¹⁴⁶ Most of the classic musculocutaneous, septocutaneous, and osteoseptocutaneous flaps can be seen as composite flaps because they basically consist of muscle or fascial plexus connecting with the skin paddle, which is dependent on the perforators originating from muscle or fascia (see Fig. 22.39).

Second is the “combined compound flap” which is a compound flap that has multiple sources and combined vascularization. There are two major subtypes – conjoined flaps and chimeric flaps – primarily differing in physical relationship of their component but retaining an independent blood supply for each component.^{41,42} The “conjoined flaps” are flaps with at least two anatomically distinct territories, each retaining their independent vascular supply but joined by means of some common physical boundary.⁴² Conjoined flaps can be further divided into two subgroups distinguished by the different source of vascularization: perforator based or branch based. The larger caliber and often subfascial or axial branches of the branch-based form may have completely unrelated origins from different angiosomes (the independent type), or these branches may arise from a common source vessel (common type) (Fig. 22.40). The “chimeric flaps” consist of multiple otherwise independent flaps that each have an independent vascular supply, but in turn all pedicles are linked to a larger common source vessel.^{42,146,147} The chimeric flap can be further divided into three subclasses: (1) perforator-based; (2) branch-based; and 3) fabricated. The fabricated component can be

Fig. 22.39 Compound flaps can be subdivided into solitary (composite) or combined types (conjoined and chimeric) based on primary source of vascularization.

Fig. 22.40 The “conjoined flaps” are flaps with at least two anatomically distinct territories, each retaining their independent vascular supply but joined by means of some common physical boundary. Conjoined flaps can be further divided into two subgroups distinguished by the different source of vascularization: perforator based or branch based. The larger caliber and often subfascial or axial branches of the branch-based form may have completely unrelated origins from different angiosomes (the independent type), or these branches may arise from a common source vessel (common type).

Fig. 22.41 The “chimeric flaps” consist of multiple otherwise independent flaps that each have an independent vascular supply, but in turn all pedicles are linked to a larger common source vessel. It is further divided into three subclasses differentiated by: (1) perforator-based, (2) branch-based, and (3) fabricated. The fabricated component can be attached to the terminus of the source vessel to the combination (sequential type) or to a branch indigenous within the flap (internal type).

attached to the terminus of the source vessel to the combination (sequential type) or to a branch indigenous within the flap (internal type) (Figs. 22.41 & 22.42). Fig. 22.43 shows a patient with tibia and soft tissue defects after trauma being reconstructed using a chimeric fabricated anterolateral thigh (ALT) perforator flap with a small strip of vastus lateralis muscle sequentially combined with contralateral fibula flap. The peroneal vessels are sequentially anastomosed to the descending branch of the lateral femoral circumflex vessel. This approach provides simultaneous transfer of multiple tissues, is able to fill large defects, allows immediate coverage, needs only one recipient vessel site, and enables a

customized approach.⁴² When planning a complex reconstruction, one should ask whether a simpler approach is sufficient and there must be unrivaled advantages to choosing the combined type of compound flap.⁴¹

Flap applications

The reconstructive elevator

Once the cause of defect is determined and relative problems solved or planned for further intervention, soft tissue

Fig. 22.42 Chimeric flaps from the subscapular artery system.

Fig. 22.44 Reconstructive ladder.

coverage is then considered. One must also consider the defect by means of the true defect size compared to the apparent defect. The concept of the reconstructive ladder was proposed to achieve adequate closure of wounds using a step-ladder approach from simple to complex procedures (Fig. 22.44). The reconstructive ladder concept was developed to establish priorities for technique selection based on the complexity of the technique and the defect requirements for safe wound closure. The ladder provides a systematic approach to wound closure, emphasizing selection first of simple and then

complex techniques, depending on local wound requirements and complexity. Direct closure represents the simplest and most straightforward technique. Direct closure may be precluded by the size of the wound or the consequences of wound tension at the closure site resulting in malalignment of adjacent tissues. When this occurs, a more complex closure technique, such as a skin graft that uses distant skin for defect coverage, is required. Although still valued and widely taught, the reconstructive ladder comes from the concept of the wound-closure ladder dating back beyond the era of modern reconstructive surgery.²⁵ A skin graft after mastectomy can still provide coverage but a pedicled TRAM (transverse rectus abdominis muscle) flap will provide superior results in addition to coverage. Now with introduction of DIEP (deep inferior epigastric perforator) flaps, the reconstructive ladder approach seems to show more flaws. In the era of modern reconstructive surgery, one must consider not only adequate closures but form and function. The reconstructive triangle emphasizes the selection of a technique that safely achieves a successful reconstruction and restores form and function (Fig. 22.45). Increased experience has led to the safe use of techniques such as flap transposition, microvascular composite tissue transplantation, and tissue expansion. The surgeon should now consider the reconstructive triangle to select the optimal technique to achieve predetermined reconstructive goals without donor site complications. Other techniques including tissue expansion, skin stretching and vacuum-assisted closure have changed the approach to reconstructive options. A simpler reconstructive option may not necessarily produce optimal results. The “reconstructive elevator” concept proposed by Gottlieb and Krieger suggests the most appropriate floor from which to choose our

Fig. 22.43 A sequential chimeric flap is used for a patient with tibia and soft tissue defect after trauma. A chimeric fabricated anterolateral thigh (ALT) perforator flap with small strip of vastus lateralis muscle sequentially combined with contralateral fibula flap is shown.

Fig. 22.45 Reconstructive triangle.

reconstruction, based on the specific requirements of the patient, the wound and the circumstances.²⁵ Thus, to provide optimal form and function, we jump up and down the rungs of the ladder. The reconstructive elevator requires creative thought and consideration of multiple variables to achieve the best form and function, rather than a sequential climb up the ladder (Fig. 22.46). This paradigm of thought does not eliminate the concept of the reconstructive ladder but replaces it as a ladder of wound closure and makes its mark in the field where variety of advanced reconstructive procedures and techniques are not readily available. Using the reconstructive elevator, the method of reconstruction should be chosen based on procedures that result in optimal form and function.

The guide for reconstruction using flaps

Flaps, whether pedicled or free, are used to reconstruct defects originating from various causes. However, despite the best efforts, necrosis can occur partially or totally to the flap. The overall survival not only depends on the proper flap selection but preoperative planning, intraoperative techniques and postoperative management involved in reconstruction.

Preoperative planning

Preoperative evaluation is the initial step for all reconstruction. One must think about the final outcome and the

Fig. 22.46 The “reconstructive elevator” concept suggests the most appropriate floor from which to choose our reconstruction, based on the specific requirements of the patient, the wound and the circumstances.

surrounding factors during the preoperative planning. Surrounding factors may include whether the patient will have psychological support, be irradiated, undergo any secondary procedures, need prosthesis, or be ambulant, among others. Once a rough plan has been postulated, the first critical step is for the surgeon to educate the patient about the procedure and the possible outcome, obtaining an informed consent.¹⁴⁸

The recipient site should be evaluated for the vertical and horizontal aspect of the defect. The vertical aspect may include subcutaneous tissues like bone, muscle, tendon, nerve, major vessels, and other deep tissues. The horizontal aspect should address the skin paddle size and the thickness of the skin flap. Added function such as functional muscle or sensate flaps should be planned based on the need of the recipient. Wound analysis includes assessment of the defect in terms of location, size and physical components. When the defect involves a significant percentage of the body surface area (e.g., burns or giant hairy nevus), the reconstructive options may be limited to skin grafts for acute coverage (e.g., burns) or sequential tissue expansion for elective reconstruction (e.g., giant hairy nevus). Complex reconstruction may need to combine various flaps as conjoined or chimeric flaps to achieve ideal reconstruction. Each component affects function and form at the defect site. Selection of a reconstructive option is based on the feasibility and relative importance of replacing each component of the defect. Preoperative planning allows designing and selecting the ideal vascular system to combine various tissues.

Systemic factors should also be considered prior to reconstruction. Obesity, smoking, hypertension, immunosuppression, heart failure, diabetes, hypercoagulability, peripheral vascular disease, chronic renal insufficiency, and others are known to be related to higher complications of donor and recipient sites including flap failure.^{149–157} However, as the development of microsurgical instruments and technique continues, well-known risk factors seem less significant in outcome of flap survival. Nevertheless, these systemic factors should be controlled to minimize not only flap-related complications but also donor site complications.^{151,153,158}

Imaging using CT (computed tomography) scans, angiograms, or MR (magnetic resonance) angiograms help to identify the vasculature of the recipient and donor site. The use of CT angiography may obtain vascular information of the recipient region without the risk of complications from arterial puncture of the groin and can also provide vascular information of the donor flap facilitating the planning and the surgical procedure.^{159,160} Fig. 22.47 shows that the descending branch of the lateral femoral circumflex artery is the collateral vessel responsible for flow to the distal leg and one should not harvest the anterolateral thigh flap based on this major collateral as it may hinder the flow to the leg. In association with prior injuries to the lower extremity, the routine preoperative use of angiogram is controversial but selectively recommended in patients who have loss of one or more peripheral pulses, a neurologic deficit secondary to the injury, or a compound fracture of the extremity that has undergone reduction and either external or internal fixation.¹⁶¹ Prior trauma or incisions may also end in damage of the vascular pedicle of the flap and thus warrant preoperative imaging to confirm the pedicle status. The use of preoperative imaging has now expanded to gather information on the pedicle of the perforator flap. It can show the emerging perforator of the superior

Fig. 22.47 The angiogram shows that the descending branches of the lateral femoral circumflex artery are the collateral vessels responsible for flow to the distal leg. This information can be vital in maintaining the flow to the distal leg and ALT flaps should not be elevated.

gluteal artery piercing the deep fascia reaching the skin. This image allows us to visualize the perforators and to select the best perforator for this flap. The CT angiogram gives information such as the caliber of the pedicle, the intramuscular course of the pedicle, location of the corresponding flap, and the subcutaneous branching from the pedicle. This information allows for more detailed preoperative planning regarding the flap. The CT angiogram remains the gold standard for preoperative imaging.¹⁶²

Hand-held Dopplers allow us to simply and quickly gather information about the perforator and the main axial vessels. However, it may lack detailed information such as the course of the perforator and the actual positive finding may not correlate clinically. Nevertheless, hand-held Dopplers remain the first-line tool to gather information regarding the pedicle of the flap. The color Doppler imaging provides better information and helps the surgeon to identify the presence of the vessels, the direction of the flow, whether the flow pattern is venous or arterial, and the flow velocity.¹⁶³

For local flaps, flap loss may result when the defect is located beyond the standard arc of rotation causing excessive tension on the vascular pedicle. Defect size beyond the vascular territory of the flap pedicle may result in either an inappropriate increase in flap dimensions or excessive flap tension at the inset site. Selection of a flap with a pedicle location in the zone of injury or use in patients with pre-existing vascular compromise may result in failure. Flap modifications, including segmental and distally based designs, are also subject to vascular compromise and potential loss. Thus, flap success is determined preoperatively based on anatomic design and on assessment of the specific reconstructive requirements.

Flap selection should be based on the defect's need for form and function. Safe and reliable muscle or musculocutaneous and fascial or fasciocutaneous flaps and perforator flaps have been described for use in all areas of the body. When design is properly based on the precise vascular territory of their vascular pedicles, the majority of flaps survive transposition to a defect. The technique selected for defect closure or reconstruction should restore normal shape or contour. Although initial experience with the musculocutaneous flaps resulted in safe wound closure, the excessive bulk was often unsightly. Frequently, a muscle flap with a skin graft provided a superior restoration of form at the recipient site. With the identification of muscle and fascial units suitable for design either as a standard transposition or microvascular composite tissue transplantation, the surgeon may select the flap best suited for defect closure. When a skin island is required, the surgeon may select a flap with a thin layer of overlying subcutaneous tissue (i.e., radial forearm flap or a perforator flap) or may plan secondary flap revision by direct excision or suction-assisted lipectomy to improve flap contour in thicker flaps. The availability of numerous flap donor sites allows selection of a technique for either standard transposition or microvascular composite/compound tissue transplantation that best restores form for reconstruction. Specialized functions at the site of reconstruction include hair growth, sensibility, skeletal support (bone), and motion (animation). Techniques of reconstruction must consider these specialized requirements. Although function restoration may require staged procedures, especially for a composite defect, it is often possible to restore all functional requirements with a single procedure. After evaluating the character of the defect, [Table 22.2](#) may guide the selection process of the flap based on circulation, composition, contiguity, construction, conditioning and conformation. The final flap design is usually delayed until dimensions of the defect is confirmed. One should think of the true defect compared to the apparent defect. An ideal reconstruction would replace defect with like tissue or with tissue that will best give the form and function.

Donor site morbidity should also be considered when selecting a flap. When possible, the donor site should be closed directly to preserve form. Use of a flap that requires a skin graft for donor site closure is justified when the flap harvested is clearly superior to alternate flaps for the defect. If it is possible to stage the flap elevation with preliminary insertion of a tissue expander, an increase in both the cutaneous flap dimensions for defect closure and the adjacent skin territory for donor site direct closure may be accomplished. Although the ultimate form at the flap recipient site remains the primary basis for flap selection, deformity due to loss of form at the donor site should be avoided when possible. Thus, reconstructive balance is achieved with selection of a tissue source to restore the defect or deformity while form and function are preserved at the donor site. In an effort to minimize donor site morbidity, many surgeons have evaluated the utility of endoscopic harvest of muscle flaps. Minimally invasive techniques for harvest of several muscles have been described. These include the latissimus dorsi, rectus abdominis, gracilis, rectus femoris, external oblique, and gastrocnemius muscles. In addition to the endoscopic harvest of muscles, laparoscopic techniques are frequently used to harvest the omentum. This has been a significant advance as the benefits include decreased scarring, less postoperative

pain and theoretically less donor site morbidity.^{164–166} Skin or perforator flaps have evolved to harvest flaps from less conspicuous sites. Although many factors are involved when choosing a perforator flap, DIEP (deep inferior epigastric perforator), SGAP (superior gluteal artery perforator), SCIP (superficial circumflex iliac artery perforator), and TDAP (thoracodorsal artery perforator) flaps are well hidden in regular clothing and have minimal donor site morbidity.

Finally, for the preoperative planning, the surgeon should always think of a plan B flap just in case plan A does not go as ideally planned. This allows preoperative visual practice, reduction of surgical time, minimizing unwanted variables, and to maintain the high spirit of motivation.^{167,168}

Intraoperative techniques

When possible the patient is positioned to allow visualization of both donor and recipient sites. This allows a two-team approach and does not need additional surgical time to change the patient's position during operation. The patient in Fig. 22.48 shows a defect on the posterior aspect of the heel pad with chronic osteomyelitis. After complete debridement, a superior gluteal artery perforator flap was used to reconstruct the heel pad without changing the patient position during surgery.¹⁶⁹ For surgeries with an expected long operating time, careful padding of potential pressure sites to avoid injury to normal structures, active warming to minimize hypothermia (which may decrease peripheral blood flow), deep vein thrombosis prophylaxis, and an intensive glucose control for diabetes are needed to ensure a positive outcome.¹⁴⁸

The recipient site must be completely ready prior to flap application. For cancer, adequate resection margins must be obtained and wounds must achieve a clean field through debridement. The design of the flap is of paramount importance. The final design of a flap intended for standard transposition, staged expansion, or microvascular transplantation should be based on the actual defect size. The original design of the flap has an impact on future procedures if the defect should recur or require further revisions. In general, flap design is delayed until adequate wound debridement or tumor resection is accomplished. If simultaneous flap elevation and resection are performed, the flap design should allow for the maximal defect size. If tissue expansion is used, the expander advancement or transposition flap should be elevated and advanced to the potential defect site before the resection is performed. Repeat expansion will be necessary if adequate tissue is not available to cover the defect created at the resection site. A careful assessment should be made of the extent of debridement required to remove nonviable structures subject to bacterial invasion and impaired vascularity. Inability to accurately predict the amount of debridement required may necessitate sequential wound debridement with subsequent wound observation and bacterial culture of the wound. When regional vascular insufficiency involving the wound site is observed, preliminary or simultaneous vascular procedures may be required in conjunction with wound debridement and coverage. The continuing debate on which flap composition is better for chronic osteomyelitis remains, but growing reports have shown that with adequate debridement, flaps – whether they be primarily muscular or skin component – can be equally effective.^{170–174} Furthermore, the skin/fasciocutaneous flaps better allow for

staged reconstructions, are easy to elevate and are less scarred and fibrotic when compared to muscle flaps. They also provide a thin flap which leads to very good aesthetic results.¹⁷⁴

Flap elevation requires precise knowledge of flap anatomy. Random pattern flaps are still used commonly in smaller wounds but as the flap gets larger, identification of the pedicle and angiosome increases the chance for success. In the case of free flaps, the recipient vessels need to be ready and patency confirmed prior to microsurgery.

When inseting the flap, tension must be avoided especially around the vascular pedicle. Postoperative swelling should be taken into account as swelling will increase tension. Meticulous coagulation of the flap as well as the recipient bed is crucial to minimize hematoma after surgery. A closed suction drain system is generally used at both the donor and recipient closure sites. One must be careful not to place the drain near the pedicle as the negative pressure of the drain may compress the pedicle.¹⁷⁵ Drains are not removed until the patient is mobilized since the resultant motion may temporarily increase the risk of seroma formation. Drains in proximity to a tissue expander or prosthetic implants are a potential source of infection and are removed as quickly as possible. When seroma drainage decreases to 20 mL in a 24-hour period, the closed drainage system is removed. When possible, drainage systems are removed by postoperative day 10 to avoid potential wound contamination through the drain exit site.

Postoperative management

Postoperative flap management is of equal importance to the success of a reconstruction. The maintenance of proper positioning, temporary immobilization, and proper dressing of the wound are critical.

Pressure on the flap base is to be avoided during the postoperative period. When possible, the area of the flap inset is elevated as in head and neck and extremity reconstruction. If the area of the flap lacks protective sensation, the site of reconstruction is placed in a nondependent position. Use of an air-fluidized bed is recommended to avoid pressure on dependent areas in patients with spinal cord injury.

Constricting bandages are avoided, particularly in the area of the flap base where pressure on the flap pedicle may compromise flap circulation. The flap is observed for potential circulatory problems during the initial postoperative period. Those patients undergoing head and neck reconstruction with microvascular tissue transfer should have strict orders to have nothing placed circumferentially around the head or neck. Nasal cannulas, oxygen masks, eye glasses, and tracheostomy collars should be avoided due to the risk of pedicle compression.

Excessive motion in the area of the flap inset is to be avoided by padding of areas adjacent to the flap inset site. In extremity reconstruction, the use of a plaster splint to immobilize the joint proximal and distal to the flap inset site is recommended. Circular casts are avoided because of the risk of pressure associated with postoperative edema and difficulty in observing flap circulation.

Perioperative antibiotics are recommended when flaps are inset at the site of contaminated defects. If an expander or permanent implant insertion site has a history of prior infection, perioperative antibiotics are also recommended. Cultures of the wound site will determine the necessity for

Fig. 22.48 Using an available flap without changing position allows for a safe and faster surgery. The patient shows a defect on the posterior aspect of the heel pad after resection of malignant melanoma (A). A flap is designed and elevated based on the superior gluteal artery along with the superficial nerve (B). Follow-up shows good contour of the heel and the donor site (C,D).

postoperative antibiotic therapy. Continued use of postoperative antibiotic therapy should be based on wound cultures and selection of culture-specific antibiotic agents.¹⁷⁶

Prolonged bed rest is avoided when possible following reconstructive surgery. With the exception of those undergoing reconstruction of the perineum and lower extremity, most patients are ambulatory after the first postoperative day. Elevation and immobilization of upper and lower extremities are generally recommended for 10 days followed by nonweight

bearing for up to 6 weeks. Weight bearing at the site of flap inset for pressure sore coverage is avoided for 4–6 weeks. Range of motion exercises at the donor site are encouraged when wound healing is complete, usually by postoperative day 7–10, to avoid joint stiffness and muscle weakness.

If the patient has difficulty regaining function at either the donor or recipient sites, a physical therapy program is recommended. Pain management for patients treated for complex defects may require consultation with a pain specialty clinic

and psychiatrist. Occupational therapy is indicated for patients unable to return to their jobs. A multi-specialty approach to patients who have undergone cancer treatment is essential to provide tumor surveillance and adjuvant therapy when indicated. Patients at risk for wound recurrence, particularly following closure of a pressure sore, and patients with spinal cord injury require instruction in avoidance of pressure and shear forces at the site of flap reconstruction and assistance in obtaining devices (i.e., wheelchair with appropriate padding) to avoid future skin injury.

Although there is no concrete evidence for the use of postoperative antithrombotic therapy, use of anticoagulation is still practiced by many surgeons and is usually of concern in microvascular tissue transplantation.²⁵ Common postoperative regimens include daily aspirin, heparin or dextran. Aspirin inactivates platelets by blocking cyclo-oxygenase. Heparin is an antithrombin III inhibitor. Dextran decreases platelet adhesiveness, inhibits platelet aggregation and decreases the blood viscosity. The use of these medications varies among surgeons.

Postoperative monitoring of a flap is a critical component in patient care after reconstruction. Many techniques have been developed to monitor flaps and have primarily focused on those flaps transferred microsurgically. These monitoring methods assess the patency of the small vessel microanastomosis. The goal is to discover any problem with the anastomosis early enough to salvage the flap. Musculocutaneous or perforator flaps, which have not been divided from their vascular pedicle, are generally monitored with clinical observation. Clinical observation generally involves assessment of skin color, tissue turgor, temperature, capillary refill, and pinprick. The ideal monitoring measure should be reliable, reproducible, sensitive, cost-effective, user-friendly, and continuous.¹⁴⁸ Adjunctive measures such as laser flowmeter, implantable Doppler, oxygen partial pressure probe, transcutaneous oxygen tension, Duplex scans, and hand-held Doppler can be used to assist the subjective monitoring of the flap.

Selection of specific flaps

Muscle and musculocutaneous flaps

After the decision has been made to use a muscle or musculocutaneous flap, the specific muscle must be chosen. General guidelines used to assist in the selection of a muscle include the following:

1. Ideally, the muscle should be adjacent to the defect.
2. The muscle should be of sufficient size and bulk to cover the defect. The final design of the flap should occur only after the defect is completely defined. When tumor exposure or wound debridement is required, the defect is often much larger and deeper than initially anticipated. By final design of the flap after debridement, costly errors in inadequate coverage can be avoided. If the defect is unstable or the margins are unclear (tumor pathology not available), wound packing or temporary skin graft coverage is warranted. One must also take into consideration that a significant amount of atrophy occurs if the origin, insertion, or motor nerve of the muscle is disrupted.
3. The muscle should be expendable. There are often synergistic muscles that can compensate for the loss of

the selected muscle so that the donor site is not impaired. However, if no synergistic muscle groups are available, either techniques to preserve donor muscle function (e.g., muscle splitting) should be employed or a different muscle chosen.

4. The status of the vascular pedicle that will sustain the proposed flap must be known preoperatively. Selective arteriography must be considered if there is a history of previous surgery in proximity to the vascular pedicle of the proposed muscle flap or if muscle paralysis is noted on physical examination. Earlier division of the motor nerve may also include ligation of the vascular pedicle. Examples of clinical situations when arteriography is particularly useful include the evaluation of the sural artery (gastrocnemius) after knee surgery, of the transverse cervical artery (trapezius) after neck and shoulder surgery, and of the thoracodorsal artery (latissimus dorsi) after axillary surgery.¹⁴⁹
5. The donor defect must be carefully considered. Some patients do not accept the use of a skin graft at the donor site, and certain muscles are more likely than others to require grafts for closure. Likewise, some patients prefer one scar site to another (e.g., the abdominal scar of the TRAM flap versus the back scar of the latissimus dorsi flap in breast reconstruction).
6. The cutaneous territory of the proposed flap must be of sufficient size and of acceptable texture. The harvested skin should be an acceptable match to the recipient site (e.g., not hair-bearing).
7. If restoration of sensation or motor function is necessary a select number of muscle, musculocutaneous and fasciocutaneous flaps are available. Common examples of muscles which provide sensation or restore function include the serratus muscle, rectus abdominis, and latissimus dorsi.¹⁷⁷⁻¹⁸¹
8. Osteomusculocutaneous flaps are available for defects in need of vascularized bone in addition to soft tissue. Examples include the trapezius flap with vascularized clavicle and scapular spine,^{150,182} pectoralis major flap with vascularized rib,^{183,184} iliac osteomusculocutaneous flap based on the ascending and transverse branches of the lateral circumflex femoral system^{167,185} and the latissimus dorsi-scapular osteomusculocutaneous flap.^{163,186}
9. The operation should be technically straightforward.

Fascia, fasciocutaneous and perforator flaps

General guidelines for choosing a specific fascia, fasciocutaneous flap and basing perforator flaps on known perforators are similar to those for muscle and musculocutaneous flaps, with a few exceptions.

The fascia, fasciocutaneous or the perforator flap must be in the proximity of the defect if a rotational/propeller flap is planned. The planned flap must be of sufficient size and bulk to reconstruct the defect. Fascia, fasciocutaneous and perforator flaps are ideal for areas that do not require bulk. The vascular supply of the area must be assessed preoperatively. If a fasciocutaneous or a perforator flap is planned, the perforating vessels should be assessed with a Doppler probe preoperatively so that the skin island can be designed. The

presence or absence of sufficient perforating vessels determines whether a specific fasciocutaneous or perforator flap can be used. Following the angiosome principle, only one adjacent territory should be included to ensure adequate vascularization of the entire flap.³³ For perforator flaps, after identifying the main perforator, other minor perforators are eventually transected at the level of the deep fascia. However, if minor pedicles are dissected together with the source vessel, the perforator flap will have a better circulation. The donor defect should be considered. These can generally be closed primarily (fascial flap) but may require skin graft if the skin island is large. Restoration of sensation with a fasciocutaneous or perforator flap is possible.

Perforator flap (free-style)

In contrast to elevating a flap on a previously identified perforator, the skin island can be selected first and the appropriate perforator located on the flap can be selected in a sequence. This is the core of the free-style approach and allows efficient handling of unexpected events which occur during flap harvest or in cases with anatomical variations.^{187,188} A specific donor or source artery does not limit the surgeon. After the location and dimension of the flap are determined and specific donor site is selected, the search for the proper perforator is performed. Although this approach provides maximum liberty for flap selection, a learning curve is required to be comfortable with this approach.¹⁸⁹

Regional application of flaps

Head and neck reconstruction

Regional flaps:

1. Temporalis
2. Sternocleidomastoid
3. Platysma.

Distant flaps:

1. Pectoralis major
2. Trapezius
3. Latissimus dorsi.

Perforator flaps

1. Facial artery perforator
2. Submental artery perforator.

Radical cancer surgery or traumatic injury can produce massive defects in the head and neck. Whereas many simple defects can be adequately treated with direct closure, local scalp flaps or skin grafts, the more complicated defect requires a larger reconstruction. The muscle, musculocutaneous and fasciocutaneous flaps play a major role in these reconstructions. Historically, large surgical defects of the head and neck were managed with staged reconstruction. Currently, the most common reconstruction involves microvascular tissue transfer.

The primary applications of the muscle or musculocutaneous flap in head and neck reconstruction include provision of tissue bulk for a significant defect (e.g., after hemimandibulectomy); protective coverage of vital structures (e.g., the carotid artery); provision of skin for intraoral lining and

coverage; and provision of skin for skull, facial, and neck defects.

The local muscle and musculocutaneous flaps for head and neck reconstruction include the temporalis, sternocleidomastoid, and platysma flaps.

The temporalis muscle is a type III, fan-shaped, bipenniform muscle. Transposition of the muscle as a turnover flap is especially useful for coverage of the orbit, superior maxilla, and ear.

The sternocleidomastoid is a type II muscle, first described in head and neck reconstruction by Owens in 1955.¹⁹⁰ This flap has historically been used for intraoral and pharyngeal reconstruction. Other uses have included augmentation of soft tissue defects of the upper neck and jaw, protective coverage of major vessels, and closure of pharyngocutaneous fistulas.^{191–193} However, of all the musculocutaneous flaps used for head and neck reconstruction, the sternocleidomastoid is considered the least reliable.^{20,193}

The platysma is a type II, thin, broad, sheet-like muscle extending over the entire anterior and lateral aspects of the neck. The use of the platysma as a musculocutaneous flap was first described in 1887 by Gersuny, who employed it in reconstructing a full-thickness defect of the cheek.¹⁹⁴ The platysma has been used for intraoral, lip, lower midface, and anterior neck reconstruction. Because of the thinness of the platysma muscle, the reconstructive surgeon must be particularly careful to avoid disrupting the muscle fibers during the dissection and placing undue tension on the vascular pedicle after transposition of the flap.

The distant muscle and musculocutaneous flaps used in head and neck reconstruction include the pectoralis major, trapezius, and latissimus dorsi flaps.

The pectoralis major is a type V, large, broad muscle. Its use as a musculocutaneous flap was first described in 1968 by Hueston and McConchie as part of a compound deltopectoral flap.¹⁹⁵ In 1977, Brown *et al.* described the use of the pectoralis major as a flap in mediastinal coverage.¹⁸ In 1979, Ariyan introduced the pectoralis major musculocutaneous flap for head and neck reconstruction (Figs. 22.49 & 22.50).²⁰ During the ensuing years, the pectoralis major musculocutaneous flap proved more valuable than the deltopectoral flap and supplanted it as the primary flap (other than microvascular tissue transplantation) in head and neck reconstruction.

The common applications of the pectoralis major musculocutaneous flap in head and neck reconstruction include the following: external resurfacing of the skin of the face and neck; intraoral and pharyngeal lining; carrying vascularized rib and skin in mandibular reconstruction; and reconstruction of the esophagus.^{196–200} Historically, the pectoralis major musculocutaneous flap has been one of the most versatile flaps used in head and neck reconstruction.

The trapezius, a type II muscle, is less widely used than the pectoralis major muscle, yet its superior location and wide anterior arc of rotation make it a valuable musculocutaneous flap.^{14,22} Modifications in design have enabled the trapezius muscle to be used as distinctly different upper and lower musculocutaneous flaps.²⁰¹ The various clinical applications of the trapezius flap have included lower facial reconstruction, especially the ear and parotid regions; lateral upper face and scalp (occipital and temporal) repair;²⁰² anterior and posterior neck reconstruction;²⁰³ orbital reconstruction with the use of an extended flap;^{204,205} and pharyngoesophageal

Fig. 22.49 Pectoralis major flap. Standard arc to middle third of face.

reconstruction. Historically, the trapezius has also been used as an osteomusculocutaneous flap, incorporating either the lateral aspect of the clavicle or the spine of the scapula (Figs. 22.51 & 22.52).²⁰⁶

The latissimus dorsi is a type V muscle originally described as a superiorly based flap by Tansini in 1896.²⁰⁷ Since the first

Fig. 22.51 Trapezius flap. Arc to face and anterior neck.

description, there have been numerous modifications and refinements of the flap. Historically, the latissimus dorsi musculocutaneous flap has been used in head and neck reconstruction for large defects or when previous irradiation or surgery precluded the use of other flaps. Since Quillen *et al.* reported the use of the latissimus dorsi as a transposition island flap in 1978 to cover the mandible and neck after resection of a tumor; various other clinical applications of the muscle have been described.²⁰⁸ In fact, the latissimus dorsi musculocutaneous flap was used frequently in intraoral and pharyngeal reconstruction.²⁰⁹ Other uses of the latissimus

Fig. 22.50 (A–C) Pectoralis major flap for head and neck reconstruction.

Fig. 22.52 (A–E) Vertical trapezius musculocutaneous flap for head and neck reconstruction.

dorsi muscle in head and neck reconstruction have included reconstruction of defects of the posterior neck, shoulder, anterior neck, lower face, occipital scalp, and intraoral-pharyngoesophageal regions.

The main impact of perforator flaps in the head and neck region is the increased capability of these flaps to accommodate complex reconstructions. The addition of perforator flaps with enhanced knowledge of vascular anatomy has allowed increased versatility in choosing an appropriate flap. The facial artery perforator flap is an example of increased choice for reconstruction of head and neck.²¹⁰ It is an evolved form of nasolabial flap and overcomes the limitations by providing a thinner flap, does not need a second procedure of dividing the flap, and provides a better rotation and mobility (Fig. 22.53). The second advantage of perforator flaps in the head and neck is the increased availability of donor site options. The submental perforator flap based on the perforator of the submental artery provides excellent texture, color match and hair-bearing properties ideal for head and neck reconstruction

(Fig. 22.54).^{211,212} The pedicle can be long as 8 cm, reaching temporal, midface, lower face as well as the oral cavity.²¹³ Depending on the laxity of the skin, it can be closed primarily and the scar well hidden in the cervicomental angle.

Breast reconstruction

Regional flaps:

1. Pectoralis major
2. Serratus anterior
3. Pectoralis minor.

Distant flaps:

1. Rectus abdominis
2. Latissimus dorsi.

Perforator flap:

1. Lateral intercostal artery perforator

Muscle and musculocutaneous flaps have had a tremendous impact on breast reconstruction and have provided women

Fig. 22.53 The facial artery perforator flap is an evolved form of nasolabial flap and overcomes the limit by providing a thinner flap, does not need a second procedure of dividing the flap and provides a better rotation and mobility of the flap.

with superior cosmetic results after mastectomy. Less aggressive surgical treatment of breast cancer such as the modified radical mastectomy, skin or nipple-sparing mastectomy, and lumpectomy have replaced the classic radical mastectomy as the treatment of choice for breast cancer. This change in

approach has resulted in smaller defects and more local tissue available for use in reconstruction. In addition, more women with pre-malignant disease or with a family history of breast cancer are undergoing prophylactic mastectomy and immediate reconstruction.

Local muscles available in breast reconstruction are the pectoralis major, pectoralis minor and serratus anterior. These muscles are especially important for patients who undergo prosthetic implant or expander insertion. For patients with an intact pectoralis major muscle and adequate overlying skin, the submuscular (subpectoral or subserratus-pectoral) placement of a prosthetic implant is a common reconstructive technique.²¹⁴ The pectoralis minor and serratus muscles can also assist in implant coverage and are generally used in addition to the pectoralis major muscle.²¹⁵⁻²¹⁷

The distant muscles available in breast reconstruction include the latissimus dorsi, rectus abdominis and a variety of other muscles transferred microsurgically including the gluteus, and fasciocutaneous perforator flaps (deep inferior epigastric perforator, superficial inferior epigastric artery and transverse upper gracilis). Distant musculocutaneous or fasciocutaneous flaps are usually indicated for patients with inadequate local tissue, unacceptable overlying skin, or radiation damage.

Fig. 22.54 The submental perforator flap based on the perforator of the submental artery provides excellent texture, color match and hair-bearing properties ideal for head and neck reconstruction.

Tansini described the earliest version of the latissimus flap.²⁰⁷ Since then, this muscle has become one of the most versatile flaps in plastic and reconstructive surgery. The advantages of the latissimus flap are that it has a reliable vascular supply and skin island and ultimately provides an acceptable cosmetic result.²¹⁸ The major drawback in using the latissimus dorsi muscle for breast reconstruction is that a prosthetic implant is usually required to provide adequate projection, as the musculocutaneous flap by itself is generally too thin.²¹⁹ Given this, the extended latissimus dorsi flap has been described; it provides additional soft tissue, thus obviating the need for implants.²²⁰ In addition, the latissimus dorsi donor scar is often unsightly and the seroma rates high.²²¹

The rectus abdominis is a type III muscle that commonly supplies a generous amount of abdominal fat and overlying skin. As a musculocutaneous flap, the rectus abdominis has proved to be one of the most valuable options for breast reconstruction. Variations in flap design have produced different types of rectus abdominis musculocutaneous flaps (e.g., vertical, transverse, bipedicle, superiorly based, and inferiorly based flaps). The flap was initially described based on its superior pedicle, the superior epigastric artery and venae comitantes, with a vertical skin island. Subsequently, its use based on the inferior pedicle, the deep inferior epigastric artery, was reported.²²² In 1982, Hartrampf *et al.* described a technique that changed the entire approach to breast reconstruction.²²³ By alignment of the skin island in a transverse direction, between the umbilicus and pelvis, the rectus abdominis musculocutaneous flap provided skin and soft tissue for breast reconstruction with improved abdominal contour. The transverse rectus abdominis musculocutaneous (TRAM) flap is now considered the musculocutaneous flap of choice for breast reconstruction (Fig. 22.55).

The indications for using the TRAM flap in breast reconstruction include a patient in need of additional soft tissue and overlying skin who has a moderate amount of lower abdominal tissue; a patient who prefers autologous tissue reconstruction without the use of a prosthetic implant; a patient who prefers a lower abdominal donor scar rather than a back scar; and a patient who has had an unacceptable result after undergoing other reconstructive methods (Fig. 22.56).²²⁴

The relative contraindications to using the TRAM flap include an extremely thin patient who has little lower abdominal tissue, a nulliparous patient in her child-bearing years, a patient with a history of abdominal wall hernia, an extremely obese patient, a heavy smoker, and a patient with lower abdominal scars. An absolute contraindication for a superiorly based transposition TRAM flap for breast reconstruction is prior division of its superior pedicle, usually related to a superior transverse laparotomy incision.

The advantages of the TRAM flap include the following:

1. It provides sufficient bulk so that a prosthetic implant usually is not required.
2. The suprapubic horizontal donor scar is aesthetically acceptable.
3. Transposition of the flap can be performed with the patient in a single operative position.
4. The skin dimensions are larger than those available with the latissimus dorsi flap.
5. A simultaneous abdominoplasty is accomplished with direct donor site closure.

The major disadvantage of the TRAM flap is that there is a potential risk of abdominal hernia or weakness after the use of the unilateral or bilateral rectus muscles for flap harvest.²²⁵

The long-term effect of the loss of one or both rectus abdominis muscles has been the subject of many investigations.²²⁶ Most studies report qualitative rather than quantitative data with regard to the postoperative strength of the abdominal wall. However, studies are beginning to show qualitative deficits of abdominal wall muscle loss.²²⁷ Overall, the majority of patients resume normal activities, without physical limitations, after breast reconstruction with the TRAM flap.

For breast reconstruction, TDAP (thoracodorsal artery perforator), AICAP (anterior intercostal artery perforator), LICAP (lateral intercostal artery perforator), and SEAP (superior epigastric artery perforator) flaps can be used as regional flaps. These regional flaps may serve to reconstruct the breast after partial mastectomy. The LICAP flap is frequently used for reconstruction for lower lateral quadrant partial mastectomy defects. They can be a simple alternative to pedicled latissimus dorsi flaps or TDAP flaps.²²⁸ The LICAP flap is supplied by the lateral branch of posterior intercostal artery found at the junction of the midaxillary line and the lower border of the corresponding rib. Perforators rising between the fourth and sixth intercostal are ideal options for partial breast reconstruction (Fig. 22.57).

Mediastinum

Regional flaps:

1. Pectoralis major.

Distant flaps:

1. Rectus abdominis
2. Latissimus dorsi
3. Omentum.

The most common reason for reconstructing the mediastinum is infection after median sternotomy. Although the incidence of infection following median sternotomy is low, reported from 0.4% to 6.9%, the morbidity and mortality are significant.²²⁹ The treatment of an infected median sternotomy wound depends on the extent of the infection and the amount of tissue necrosis. Historically, the standard therapy for an infected median sternotomy wound included debridement and closed tube irrigation. Muscle flap coverage was generally reserved for wounds recalcitrant to standard therapy. Now, it is generally accepted that early muscle flap transposition decreases morbidity, and therefore the use of a muscle flap should always be considered for the treatment of median sternotomy wounds.

The preferred local muscle for mediastinal coverage is the pectoralis major. In 1980 Jurkiewicz *et al.* described the use of the pectoralis major muscle flap to obliterate the sternal-mediastinal dead space.²³⁰ The pectoralis major can be mobilized in several ways. The muscle can be transposed either on the dominant thoracoacromial pedicle or as a turnover flap on the segmental secondary vascular pedicles (perforating vessels from the internal mammary artery and vein). Nahai *et al.* described a modified technique of the turnover flap that preserves the lateral one-third of the muscle based on the dominant vascular pedicle and its motor nerves.²³¹ The advantage of this technique is the preservation of the anterior

Fig. 22.55 Various designs of superiorly pedicled TRAM flaps.

Fig. 22.56 (A–C) TRAM flap breast reconstruction.

axillary fold. The pectoralis muscle flap remains the mainstay of treatment in both adults and children with sternal wound infections.^{232–234}

Depending on the size of the defect, the surgeon can use one or both pectoralis major muscles for coverage.²³⁵ If additional coverage is needed, the rectus abdominis can be used

along with the pectoralis major muscles to cover the inferior aspect of the wound.²³⁶ Used as either a muscle or musculocutaneous flap, the rectus abdominis muscle is a reliable source for inferior mediastinal coverage; in addition, it provides the ability to fill a large dead space.^{237,238} In considering the use of the rectus abdominis muscle, it must be noted that the superior epigastric artery is the continuation of the internal mammary artery inferior to the sternum that should be avoided during debridement of the sternal wound. Furthermore, the use of the internal mammary artery as a coronary artery bypass graft may adversely affect perfusion of the superiorly based rectus abdominis flap, which precludes the use of the rectus flap on that side. Collateral circulation to the internal mammary vessels distal to the site of ligation during coronary bypass will generally allow adequate perfusion through the superior epigastric artery and vein for superior transposition to the mediastinum (Figs. 22.58 & 22.59).

The omentum is an alternative source of tissue available to be transferred for mediastinal reconstruction; it may be used solely or in combination with another flap.²³⁹ The omentum can be based on the right or left gastroepiploic vessels. In view of the risk of exposing the peritoneum to a contaminated field, however, the omentum is generally reserved for patients in whom the pectoralis major and rectus abdominis muscles are unavailable.²⁴⁰ The harvest of the omentum has been achieved laparoscopically to lower the potential abdominal wall morbidity.²⁴¹

The latissimus dorsi provides another alternative muscle or musculocutaneous flap for coverage of the upper mediastinum.²⁴² Its use is usually indicated when the pectoralis major is absent or damaged by previous incisions or radiation therapy.²⁴³ The advantage of using the latissimus dorsi muscle or musculocutaneous flap is that the vascular pedicle and the donor site are distant to the infected area.²⁴⁴ The disadvantages include the inconvenience of obtaining a muscle flap from the back and that the latissimus dorsi muscle may be too thin for the deeper, more extensive mediastinal defects. The latissimus dorsi can also be transferred microscurgically to sternal wound defects.²⁴⁵

Chest wall and pulmonary cavity

Regional flaps:

1. Pectoralis major
2. Latissimus dorsi
3. Serratus anterior.

Distant flaps:

1. Rectus abdominis
2. Omentum.

Perforator flaps

1. TDAP (thoracodorsal artery perforator)
2. Keystone flaps.

Reconstruction of the chest wall is challenging. Ablative surgery for neoplasm, infection, radiation, and trauma can produce extensive full-thickness chest wall defects. Furthermore, many of the patients in need of reconstruction have previously undergone some form of chemotherapy or high-dose irradiation for their primary disease. Wound healing can therefore be severely compromised at the time of reconstruction.

Historically, methods of chest wall reconstruction consisted of various random and tube flaps that often required several stages before completion. Currently, the reconstruction of the chest wall is successfully accomplished without the need for delay or staged procedures. Partial thickness defects with

Fig. 22.57 The LICAP flap is supplied by the lateral branch of the posterior intercostal artery found at the junction of the midaxillary line and the lower border of the corresponding rib. Perforators rising between the fourth and sixth intercostal are ideal options for partial breast reconstruction.

viable muscle at the wound bed can be managed with skin grafting; larger full-thickness defects require flap reconstruction. In addition to flap reconstruction, Prolene® mesh is indicated for chest wall reconstruction to provide stability and support for the overlying flap when there is significant loss of chest wall continuity.^{246,247}

The pectoralis major and latissimus dorsi muscle and musculocutaneous flaps are the most commonly used in chest wall reconstruction. Larson and McMurtrey stated that the pectoralis major musculocutaneous flap is the flap of choice for defects of the lower neck and upper third of the sternum, whereas the latissimus dorsi musculocutaneous flap is preferred for wounds of the anterior chest wall that will require removal of two or three ribs and resection of <8 cm of skin. In these authors' series of 53 flaps in 50 patients, the musculocutaneous flap alone provided adequate support and stability. Fascia, ribs, and prosthetic mesh were not needed for support.²⁴⁸

The use of the latissimus dorsi flap in a patient who has previously undergone a thoracotomy decreases the reliability of the pedicle and safety of subsequent ipsilateral flap transposition although previous thoracotomy is not an absolute contraindication. In fact, Scheffan *et al.* reported that a standard anterolateral thoracotomy, which separates the latissimus

Fig. 22.58 Pectoralis major flap. (A) Standard flap to anterior mediastinum based on thoracoacromial pedicle. (B) Turnover arc to anterior mediastinum based on perforator vessels from internal mammary artery and associated veins.

Fig. 22.59 (A–E) Bilateral pectoralis muscle flaps for mediastinal reconstruction.

dorsi into an upper third and lower two-thirds, does not preclude the subsequent use of the muscle as a flap.²⁴⁹ More recently, the latissimus dorsi muscle has been used successfully in patients who had undergone previous posterolateral thoracotomy.²⁵⁰ The upper third of the latissimus dorsi muscle, based on the thoracodorsal pedicle, may be used to cover superior anterolateral chest wall defects. The lower two-thirds of the muscle, based on its secondary pedicles from the paraspinal perforators, can be used as a reverse latissimus dorsi flap with or without the overlying skin to cover inferolateral and posterior chest wall defects. Early work by McCraw *et al.* and Bostwick *et al.* was instrumental in the development of the reverse latissimus dorsi flap.^{251,252} Latissimus dorsi muscle and musculocutaneous flaps have proved invaluable in the treatment of numerous chest wall and pulmonary cavity disorders including Poland syndrome,^{253,254} spina bifida defects,^{255,256} and diaphragmatic hernias.^{257,258}

The serratus anterior muscle can also be useful as a local muscle flap for chest wall and pulmonary cavity

reconstruction. The serratus muscle has a constant and reliable vascular pedicle and a long arc of rotation.²⁵⁹ Arnold *et al.* described its use in reconstructing the chest wall, closing bronchopleural fistulas, and reinforcing tracheal reconstructions.²⁶⁰ The serratus may be surgically split thereby utilizing only a portion for reconstruction.⁴⁴

The rectus abdominis muscle is a distant muscle or musculocutaneous flap for chest wall reconstruction. Larson *et al.* showed that the rectus abdominis musculocutaneous flap is particularly useful for large chest wall defects.²⁴⁸ The availability of the flap is dependent on the status of the internal mammary arteries. Miyamoto *et al.* favored the rectus abdominis musculocutaneous flap over the latissimus dorsi in chest wall reconstruction because of its convenience (the patient can remain in one position intraoperatively), ease of elevation and subsequent closure of the donor site.²⁶¹ In addition, it is thought that in situations when up to three ribs are removed and reconstructed with mesh, the rectus shows a distinct advantage given its thickness which

minimizes the risk of creating a flail chest wall.²⁶² Large defects of the chest wall within the arc of rotation of the rectus can be reconstructed. The rectus abdominis muscle may be used as a transverse or vertically oriented musculocutaneous flap.²⁶³

If the internal mammary vessels have been manipulated the rectus flap is often transferred microsurgically.²⁶⁴

The omentum is also utilized for chest wall reconstruction. The omentum can be harvested laparoscopically, obviating the need for a large abdominal incision. When used as a transpositional flap, the omentum can be based on either the right or left gastroepiploic vessels. The omentum has a large surface area, obliterates dead space, is pliable, and contains angiogenic and immunogenic properties. The use of the omentum in chest wall reconstruction secondary to osteo-radionecrosis, cancer ablation, and chronic wounds is well established.⁷⁹

The regional perforator flaps are often with short pedicle around the chest. The TDAP flap does have a long pedicle making reconstruction possible in the upper two thirds of the chest wall. However, the frequent presence of dead space may require additional muscle mass favoring the latissimus musculocutaneous flap. The keystone island flap based on fasciocutaneous and musculocutaneous perforators offers robust vascularity of perforator flaps and the ease and speed of simple local flap advancement.³²

Abdominal wall

Regional flaps:

1. Rectus abdominis
2. External oblique.

Distant flaps:

1. Tensor fascia lata
2. Latissimus dorsi
3. Rectus femoris.

Perforator flaps:

1. Anterolateral thigh (ALT)
2. Deep inferior epigastric artery perforator (DIEAP)
3. Deep superior epigastric artery perforator (DSEAP)
4. Propeller.

In reconstructing abdominal wall defects, the surgical objective is to provide soft tissue coverage in addition to re-establishing the abdominal wall integrity. To plan safe and reliable techniques for wound closure, it is helpful to classify complex wounds by location and the status of the overlying skin and soft tissue coverage. In regard to location, the abdominal wall is divided into four zones: zone 1A, upper midline defects with extension across the midline; zone 1B, lower midline defects with extension across the midline; zone 2, upper quadrant defects; and zone 3, lower quadrant defects (Fig. 22.60, Table 22.14).

The two muscles available for local flaps are the rectus abdominis and the external oblique. The rectus abdominis muscle or musculocutaneous flap is the flap of choice for unilateral abdominal wall defects. In 1977 Mathes and Bostwick described the use of the rectus abdominis musculocutaneous flap for reconstruction of an abdominal wall defect.²²² Parkash and Ramakrishnan reported the use of a rectus abdominis musculocutaneous island flap for coverage of an extensive radionecrotic abdominal wall ulcer that had been

Fig. 22.60 Reconstructive zones of the abdomen.

resistant to conservative therapy.²⁶⁵ In 1983, Taylor *et al.* described the extended deep inferior epigastric flap, which consists of an inferiorly based rectus abdominis musculocutaneous flap with a superolateral fasciocutaneous extension. With this larger skin territory, extensive defects of the abdomen, as well as those of the groin and thigh, have been successfully treated.²⁶⁶

The rectus may be released from its lateral attachments to achieve midline abdominal wall closure. Several variations have been described. One variety, termed separation of components, involves separation of the external oblique fascia with an incision just lateral to the linea semilunaris allowing a plane to develop between the external and internal oblique muscles.²⁶⁷ This permits medial mobility of the rectus abdominis muscle. Other variants of sliding myofascial partitions or releases have been used successfully to reconstruct the abdominal wall.^{222,268} Alternatively, the rectus may be used as a turnover flap to achieve closure.²⁶⁹

The external oblique muscle may be used to reconstruct absent or deficient rectus fascia.²⁷⁰ The external oblique musculocutaneous flap is an alternative local flap, useful for

Table 22.14 Flaps for abdominal reconstruction by location (zone)

reconstructing small, full-thickness upper abdominal wall defects.^{271–273} The external oblique musculofascia may also be expanded and advanced centrally to repair abdominal wall defects.^{274,275}

The distant muscle and musculocutaneous flaps used in abdominal wall reconstruction include the latissimus dorsi, tensor fascia lata, and rectus femoris flaps. Transposition of the latissimus dorsi musculocutaneous flap is a reliable technique that is particularly useful for superolateral abdominal wall defects.^{276,277} This flap is particularly useful in traumatic defects, burn injuries and post-extirpative defects.^{278–280} The latissimus dorsi can also be transferred microsurgically to cover central abdominal defects.²⁸¹ This flap may also be reinnervated and has shown enough contractile capacity and strength to adequately replace the function of the missing abdominal wall muscles.²⁸²

The use of the tensor fascia lata (TFL) as a musculocutaneous and musculofascial flap is indicated for lower abdominal wall reconstruction. Wangenstein initially described use of this flap for lower abdominal wall closure.²⁸³ The unique qualities of the tensor fascia lata flap include the large amount of vascularized fascia and skin and the low donor site morbidity.^{284–286} The TFL is most commonly used as a rotational flap, although success as a free flap has been demonstrated.²⁸⁷ As a rotational flap, the arc of rotation is limited to the lower abdominal wall, whereas when used as a free flap, any region of the abdominal wall may be reconstructed.²⁸⁸

The rectus femoris musculocutaneous flap is a dependable alternative flap for abdominal wall reconstruction.^{289,290} Variations of the rectus femoris flap, including the use of fascial extensions and tissue expansion, have been described to extend its arc of rotation.^{291,292} However, it tends to be bulkier than the TFL and has greater donor site morbidity. Leg extension may be adversely affected with the use of this flap although subsequent studies show no appreciable effect.^{291,293} In certain instances the rectus femoris is preferred to the TFL flap. An example would be the use of the rectus femoris to treat a radionecrotic ulcer involving the lower abdominal wall, given the need for muscle bulk to fill the defect (Fig. 22.61).²⁹⁴

There can be many options for perforator flaps to cover the abdomen. For moderate or small-sized wounds, a perforator can be found near the defect and the flap can be rotated as a propeller flap to cover the skin defect of the abdomen. This rotation based on the perforator allows rotation of the flap without violating the structures beneath the deep fascia.⁵⁸ For larger and complex wounds, a larger perforator flap or a flap with composite tissue can be used. Fig. 22.62 divides the abdomen into five zones showing the preferred perforator flap for reconstruction.⁵⁸ The DIEP flap can be rotated as a propeller to cover the lower abdomen as well as the mid abdomen. If there is a scar within the flap territory, it may jeopardize the flap circulation after elevation. A pedicled ALT flap can be harvested with large dimensions able to reach the low and lateral abdomen. The ALT can be elevated with a deep fascia as a composite flap to restore the integrity of the abdominal wall.²⁹⁵ The DSEAP flap can be designed horizontal and slightly obliquely parallel to the costal margin. A propeller-style harvest and rotation can be done to reconstruct the upper abdominal region.⁵⁸ When elevating this flap, one should always confirm the presence of the internal mammary artery as this is the main source vessel of the perforator.

Groin and perineum

Regional flaps:

1. Sartorius
2. Pudendal thigh flap.

Distant flaps:

1. Gracilis
2. Tensor fascia lata
3. Rectus femoris
4. Rectus abdominis
5. Gluteus maximus.

Perforator flaps

1. Free-style perforator.

Reconstruction of the groin and perineum is often indicated for defects due to trauma, tumor resection and infection. The wounds can be extensive and, because of their proximity to the anus and urethra, are susceptible to fecal and urinary contamination. In addition, wounds involving the groin may expose the femoral vessels. Vascular prosthetic grafts and adjunctive radiation therapy in the cancer patient can further compound the problem.

The sartorius is a type IV muscle with multiple segmental vascular pedicles that limit its arc of rotation. The division of one or two of the most proximal pedicles, however, enables the superior aspect of the sartorius muscle to be transposed medially into the groin. This technique is used for coverage of exposed femoral vessels and prosthetic vascular grafts.²⁹⁶

The pudendal thigh flap is an axial pattern, sensate fasciocutaneous flap based on the terminal branches of the internal pudendal artery.^{297,298} Variants of this flap are gluteal fold flaps, lotus flaps, and Singapore flaps.^{297,299,300} Various designs can be used: along the longitudinal axis in the line of the internal pudendal artery in the gluteal fold, a V-Y advancement, and a rhomboid-style flap.

The gracilis is a type II muscle that has both an anterior and posterior arc of rotation. Anteriorly, the muscle can be used for groin and perineal reconstruction; posteriorly, ischial and perirectal defects can be reconstructed.^{301–303} Other common uses of the gracilis muscle and musculocutaneous flap include reconstruction of the vagina, penis, scrotum, and anal sphincter (Fig. 22.63).^{294,304–306}

The tensor fascia lata (TFL) is particularly useful for groin and perineal reconstruction.^{307,308} It can be used as either a musculocutaneous flap or a musculofascial flap. The TFL is also used in vulvar reconstruction and recurrent inguinal hernia reconstruction.²⁸⁴

The rectus femoris is useful for coverage of the groin and perineum.^{309,310} It is a large, bulky muscle that has an arc of rotation similar to that of the tensor fascia lata. Despite its reliability and desirable muscle bulk, this muscle is generally used as an alternate flap in the ambulatory patient, given the potential functional deficit associated with its harvest, although more recent evidence suggests that the results of the reconstruction appear to outweigh the loss of strength.^{284,311}

The rectus abdominis muscle or musculocutaneous flap based on its inferior pedicle provides a reliable flap for defects of the anterior pelvis and groin.^{222,294,312} Its wide arc of rotation and abundant blood supply through the inferior epigastric vessels make it an excellent reconstructive flap for this region. The vertical rectus abdominis musculocutaneous

Fig. 22.62 The five zones of the abdomen are the periumbilical hub (green), the epigastric (red), left and right lateral (yellow), and infraumbilical (blue). They are shown with the preferred perforator flap for cutaneous coverage inscribed. ALT, anterolateral thigh; DIEAP, deep inferior epigastric artery perforator; DSEAP, deep superior epigastric artery perforator. (From Blondeel PN, Morris SF, Hallock GG, Neligan PC. *Perforator Flaps*, 2nd edn. St. Louis: QMP; 2013.)

flap is useful for large, irradiated defects in the perineum (Figs. 22.64 & 22.65).^{178,313,314}

The gluteus maximus muscle provides stable coverage for pelvic and perineal defects. Its large mass is particularly useful for obliterating pelvic dead space and covering perineal wounds; it is also useful for rectal sphincter reconstruction.^{315,316} The gluteus maximus fasciocutaneous V-Y advancement flap is reliable for extensive vulvectomy and recurrent rectal cancer defects (see Fig. 22.63).^{317,318} The gluteal thigh flap, described by Hurwitz, includes the inferior part of the gluteus maximus muscle and a large cutaneous territory of the posterior thigh that is supplied by the descending branch of the inferior gluteal artery.³¹⁹ The gluteus maximus musculocutaneous and gluteal fasciocutaneous flap is particularly useful for reconstructing deep perineal and pelvic defects.^{320,321}

Often perineal reconstruction can be complex, requiring multiple flaps. One must decide the best choice of reconstruction as well as considering ideal donor sites. Due to the rich available perforators of this region, many new flaps and approaches have been introduced.^{322,323} These perforator flaps can originate from the external and internal pudendal artery, obturator artery, deep inferior epigastric artery, inferior gluteal artery, descending branch of medial circumflex femoral artery, and more. One can design a single or a multiple perforator flap based on these perforators and tailor the reconstruction according to the needs of the defect. This free-style approach

allows choosing a well-vascularized skin flap, thin flap, provides a variety of flap design, and minimizes donor site morbidity.

Lower extremity

Regional flaps:

1. Gastrocnemius
2. Soleus.

Distant flaps:

1. Cross-leg.

Perforator flaps:

1. Propeller flap
2. Distally based perforator flaps
3. Medial sural artery perforator (MSAP).

Reconstruction of the lower extremity remains particularly challenging. Defects including exposed joints and prostheses, infected bone, and fractures are common. Furthermore, the availability of adequate soft tissue for coverage is limited, particularly in the lower third of the leg.

There are two local sources of muscle or musculocutaneous flaps available for reconstruction of the leg, the gastrocnemius and the soleus muscles. The use of distant flaps involves microvascular transplantation of various muscles or perforator flaps depending on the size of the wound and surgeon's preference. Many muscles have been described, including the gracilis, latissimus dorsi, and rectus abdominis. In an effort to minimize donor site, the anterolateral thigh flap, deep inferior epigastric perforator flap and the superficial inferior epigastric artery perforator flaps may be used as well. Cross-leg flaps are also available but have largely been supplanted by either local muscle flaps or microvascular composite tissue transplantation.

The gastrocnemius is a type I muscle, consisting of a medial and a lateral head. Each head has a wide arc of rotation based on its single vascular pedicle (medial or lateral sural vessels). The gastrocnemius muscle or musculocutaneous flap is the flap of choice for coverage of the knee and for coverage of exposed bone or orthopedic hardware involving the upper two-thirds of the leg.^{324,325} Defects of the middle third of the leg can also be reconstructed with the gastrocnemius muscle.^{326–328} In patients with radical knee debridement and loss or disruption of the extensor mechanism, the gastrocnemius can be used to restore knee function (Figs. 22.66–22.67).³²⁹

The soleus muscle flap is utilized for reconstructing defects involving the middle third of the leg. The soleus muscle is the prime ankle plantar flexor and it serves to stabilize the ankle in ambulation by opposing dorsiflexion.³³⁰ Because of compensatory mechanisms, the use of the soleus muscle as a flap does not impair function. Function-preserving techniques such as muscle splitting is recommended if the soleus is used in a patient who does not have a functional medial and lateral gastrocnemius muscle.^{331,332} Defects of the proximal third can be reached by the soleus, but require extensive mobilization of the muscle.³³³ In the lower third of the leg, the soleus muscle can be used as a proximally or distally based flap. In this region, however, the soleus muscle flap is generally used for smaller defects (Fig. 22.68). Larger defects require microvascular tissue transplantation.

Fig. 22.63 (A–D) Bilateral gracilis and gluteal thigh flaps for reconstruction of a radiation defect of the perineum.

Fig. 22.64 Rectus abdominis flap. (A) Arc to perineum. (B) Arc to internal pelvis.

Fig. 22.65 (A–E) Rectus abdominis musculocutaneous flap for groin coverage.

For small and moderate-sized defects with less extensive dead space, a skin flap can be considered to restore function and form. The donor site is usually limited to the same extremity and the abundant perforators allow tailored reconstruction. The propeller flap based on a single perforator can be elevated as a fasciocutaneous or a skin flap harvested above the fascia. The flap is designed around a perforator as a pivot point and forming two blades with an unequal length that can be rotated to fill the defect (Fig. 22.69). The ability to rotate up to 180° makes it versatile for thigh and lower leg defects. Fig. 22.70 shows a free-style perforator-based propeller flap on the upper thigh rotated to reconstruct the mid posterior thigh defect after cancer resection. An adequate flap length can be secured by dissecting further into the source vessel when needed, injury to the perforator avoided with meticulous dissection, identification of a perforator with a good pulse, surrounding tissues around the perforators sufficiently released to minimize kinking, and supercharge or turbocharge veins located distally in the flap to reduce venous congestion. Although not ideal, skin graft on the donor site

may be needed when used in the lower leg. Nevertheless, the simplicity and versatility of this approach may justify the additional donor site morbidity. Some perforator flaps can be extended by making them reverse pattern/distally based flaps. When an ALT is elevated on a proximally located perforator and raised as a reverse pattern, the flap can easily reach the distal part of the knee.^{334,335} The MSAP flap is another flap that can reach the knee as a regional perforator flap. When a line is drawn from the midpoint of the popliteal crease to the apex of the medial malleolus, the first perforator from the medial sural artery usually rises from a semicircle with a 2 cm radius centered 8 cm distal to the popliteal crease (Fig. 22.71).³³⁶ With an average length of 8 cm, the flap can easily reach the knee.

Foot

Regional flaps:

1. Flexor digitorum brevis
2. Abductor hallucis

Fig. 22.66 Gastrocnemius flap. Arc to knee and upper third of leg.

Fig. 22.67 (A–D) Gastrocnemius musculocutaneous flap for knee and proximal third of tibia defect.

Fig. 22.68 Soleus flap. (A,B) Arc to middle third of leg.

3. Abductor digiti minimi

4. Lateral calcaneal artery flap.

Defects of the foot are most often due to trauma or the long-standing effects of underlying systemic disorders such as diabetes mellitus and peripheral vascular disease. These wounds can be extremely difficult to treat and often are best left uncovered until the underlying disease is treated (e.g., by revascularization). For some patients with severe, irreversible underlying systemic disease, local conservative wound care may be the only appropriate form of therapy.

When reconstruction is necessary, several issues must be addressed, such as the size of the defect and the patient's

vascular, neurosensory, and weight-bearing status. For small defects, skin grafts are often the procedure of choice provided that there is adequate protective soft tissue within the bed of the defect. For small defects involving weight-bearing areas, axial innervated skin flaps and fasciocutaneous flaps have been successful in providing stable coverage.^{143,337} For the deeper, more extensive foot defect, the use of a muscle or musculocutaneous flap is usually necessary. The local muscles available for use as flaps include the flexor digitorum brevis, the abductor hallucis, and the abductor digiti minimi. These muscles are small and are inadequate for larger defects. The use of a distant muscle (e.g., cross-foot flap) or microvascular free tissue transfer is usually necessary for coverage of any major wound (those with excessive size and depth or with component loss).

Mathes *et al.* demonstrated the anatomy of the flexor digitorum brevis for use as a flap in 1974.¹⁵ It is a type II muscle that measures approximately 10×4 cm. This muscle was then shown to be clinically useful to cover a calcaneal defect in 1974 by Vasconez *et al.*¹⁹ In 1980, Hartrampf *et al.* described a modification of this technique, using the muscle as an island flap that increased the arc of rotation. As an island flap based on the lateral plantar artery, the flexor digitorum brevis muscle reaches the malleolus and can cover the entire postero-superior aspect of the heel pad.³³⁸ The authors recommended that the patency of both the dorsalis pedis and the tibialis posterior artery should be confirmed before the lateral plantar artery is divided. In patients who have occlusion of either the dorsalis pedis or the tibialis posterior artery, the lateral plantar artery serves as a vital conduit of collateral flow and should not be divided for flap use. The flexor digitorum brevis, when transposed as a muscle flap, may provide stable coverage and is of benefit in both diabetic and nondiabetic patients (Fig. 22.72).^{339,340}

Fig. 22.69 The propeller flap based on a single perforator can be elevated as a fasciocutaneous or a skin flap harvested above the fascia. The flap is designed around a perforator as a pivot point and forming two blades with an unequal length that can be rotated to fill the defect.

Fig. 22.70 A patient is shown with a defect after sarcoma resection of the posterior aspect of the mid thigh. A perforator is mapped out using Doppler nearest to the defect (A). After checking the status of the perforator (B), a free-style perforator-based propeller flap on the upper thigh is designed, elevated and rotated to reconstruct the mid-posterior thigh defect (C,D).

Fig. 22.71 The MSAP flap. The illustration shows that the first perforator is usually detected 8 cm from the midpoint of the popliteal crease within a distal half circle drawn with a 2 cm radius. m, medial malleolus; p, midline of popliteal crease. (Adapted from Kim HH, Jeong JH, Seul JH, Cho BC. New design and identification of the medial sural perforator flap: an anatomical study and its clinical applications. *Plast Reconstr Surg.* 2006;117:1609–1618.)

The retrograde lateral plantar artery flap was described by Reiffel and McCarthy in 1980.³⁴¹ The flap is fashioned by dividing the lateral plantar vessels proximally; the plantar fascia and the flexor digitorum brevis muscle can be elevated as a flap based on distal retrograde flow. This flap is particularly useful for coverage of medial and lateral metatarsal head defects.³⁴²

The abductor hallucis is a type II muscle with branches of the medial plantar artery as its dominant vascular supply.¹⁵ Based on this vascular pedicle the abductor hallucis can be elevated as a muscle or musculocutaneous flap, and it can reach defects just inferior to the medial malleolus as well as defects of the proximal medial aspect of the dorsum of the foot. Like the lateral plantar artery, the medial plantar artery should not be divided if either the dorsalis pedis or the posterior tibial artery is occluded. The abductor hallucis muscle flap may be distally based to reconstruct forefoot defects.³⁴³

Fig. 22.72 Flexor digitorum brevis flap. Arc to heel.

The abductor digiti minimi is a type II muscle with branches of the lateral plantar artery as its dominant vascular pedicle.¹⁵ This small muscle based on its dominant pedicle can reach defects adjacent to the lateral malleolus. However, because of its size, the flap is limited in its ability to provide coverage of larger defects. In 1985, Yoshimura *et al.* reported the use of a distally based abductor digiti minimi muscle flap.³⁴⁴ This muscle flap based distally on the communication between the lateral plantar artery and the plantar arch can be used to cover small defects of the distal half of the foot. The abductor digiti minimi may be harvested with the lateral calcaneal artery sensate skin flap to cover plantar heel wounds.³⁴⁵

The lateral calcaneal artery is the terminal branch of the peroneal artery. The flap can be designed as a fasciocutaneous peninsula flap 4 cm wide extending from lateral malleolus to anterior Achilles tendon. The flap can extend vertically from lateral malleolus to the plantar surface of heel.^{346,347} After the transposition of the flap, the donor site frequently needs skin graft coverage.

Posterior trunk

Regional flaps:

1. Trapezius
2. Latissimus dorsi
3. Gluteus maximus
4. Scapular and parascapular
5. Paraspinous muscle.

Perforator flaps:

1. Intercostal artery perforators
2. Lumbar artery perforators.

The regional flaps used for reconstruction of midline and posterior trunk defects include three pairs of posterior trunk muscles: trapezius and latissimus dorsi muscle flaps for the upper and mid posterior trunk defects and the latissimus dorsi and gluteus maximus muscle turnover flap for the lower posterior trunk (Fig. 22.73). All three muscles have large cutaneous territories that allow them to be used as musculocutaneous flaps.³⁴⁸ In addition, other options include the scapular flap, parascapular flap, and the paraspinous muscle flap (Table 22.15). The selection for each of these regional muscle flaps must be made first by evaluating the defect and then selecting the relevant flap based on the understanding of the anatomy and the arc of rotation. These approaches may end up with too much tension and poor tissue vascularity of the flap that may be designed beyond the angiosome territory. In complex cases, it may require multiple flap or two-layered reconstruction resulting in increased risk of donor site morbidity.³⁴⁸ It can be critical for patients that may undergo radiation therapy to heal properly after the initial reconstruction. Although there are multiple muscle groups in the posterior trunk, reconstruction remains difficult using regional flaps.

The concept of perforators has allowed a new dimension in reconstructive surgery. It defines the vascular supply for a skin island from a single perforator penetrating the deep muscle fascia while sparing tissues surrounding the pedicle. The propeller flap intentionally rotates the flap based on a single perforator resulting in an effective transposition.^{59,60,349} By designing with accuracy, this perforator-based propeller flap can be used locally to cover various defects of the back without injuring muscle function, provides sufficient bulk to obliterate dead space, and can be closed primarily leading to minimal donor site morbidity (Fig. 22.74).¹⁸⁸ With the understanding that any perforator can be used as a flap, the free-style flap leads to flexible design of propeller flaps enhancing the chance for prompt reconstruction. The two major vascular systems of the back are from the intercostal artery and the lumbar artery perforators. According to the report by Saint-Cyr's group, in the lumbar region, two major areas of

Table 22.15 Regional flaps for posterior trunk midline defects	
Wound location	Muscle flap
Cervical	Trapezius muscle flap Latissimus dorsi flap
High thoracic Small defect Large defect	Trapezius muscle with split-thickness skin graft Latissimus with skin island Trapezius muscle (deep layer)
Thoracic Small defect Large defect	Latissimus advancement flap Reverse latissimus dorsi flap Paraspinous turnover flap Latissimus dorsi with skin island
Thoracolumbar and low lumbar	Latissimus dorsi with skin island Unipedicled latissimus Composite latissimus and gluteus maximus Paraspinous turnover flap

Fig. 22.73 (Left) The common flaps that can be used to reconstruct an upper thoracic cervical defect include (A) the trapezius muscle flap and (B) the latissimus dorsi flap. (Center) the common flaps that can be used to reconstruct a midthoracic defect include the (A) trapezius muscle flap, (B) latissimus dorsi flap, and (C) paraspinous turnover flap. (Right) Defects in the lower lumbar area can be reconstructed with (A) a reversal latissimus dorsi flap with skin island, (B) a composite latissimus and gluteus maximus flap, or (C) a superiorly based gluteus flap. (Adapted from Mathes DW, Thornton JF, Rohrich RJ. *Management of posterior trunk defects*. *Plast Reconstr Surg*. 2006;118:73e–83e.)

perforators are clustered within 10–20 cm of the coccyx and 10 cm from the midline. In the thoracic region, perforator location is clustered similarly distant from the midline at 10 cm, and 0–15 cm from C7.³⁵⁰ Any one of these perforators can be based as a perforator flap but the perforator with the strongest pulse and diameter may have a better flow to the skin flap and may be the preferable choice as pedicle.³⁵¹ Other sources can be perforators from the superior epigastric artery, deep inferior epigastric artery, superficial inferior epigastric artery, superior circumflex iliac artery, deep circumflex iliac artery and the superior gluteal artery.^{350,352} In cases where a large dead space is present, one can epithelialize the skin flap to obliterate it. Multiple perforator flaps can be elevated and rotated if the defect is too large for a single flap application.³⁵³

Pressure wounds

Regional flaps:

1. Gluteus maximus.

Distant flaps:

1. Tensor fascia lata
2. Gracilis
3. Hamstrings
4. Omentum.

Perforator flaps:

1. Sacral region:
 - Superior gluteal artery perforator (SGAP)
 - Inferior gluteal artery perforator (IGAP)
 - Lumbar artery perforator (LAP)
 - Parasacral artery perforator (PSAP)
 - Lateral intercostal artery perforator (LICAP)
2. Ischial region:
 - Inferior gluteal artery perforator (IGAP)
 - Adductor perforator
3. Trochanteric region:
 - Anterolateral thigh (ALT) perforator
 - Profunda femoris artery perforator (PFAP).

The gluteus maximus is a regional flap commonly used for the surgical treatment of pressure sores. It is a type III muscle and it is the flap of choice for reconstructing deep sacral and ischial pressure sores. Function-preserving techniques such as bilateral advancement flaps using only the superior halves of the gluteus maximus for sacral coverage are recommended for the ambulatory patient.^{49,354,355} Variations in technique, including the sliding gluteus maximus flap, the transposition gluteus maximus flap, and island flaps based on

Fig. 22.74 Freestyle propeller flaps based on a single perforator with accurate design allows coverage of various defects of the back without injuring muscle function, provides sufficient bulk to obliterate dead space and can be closed primarily leading to minimal donor site morbidity. A patient with a defect of the upper back is shown (A). After identifying a perforator using Doppler, the design is completed to cover the defect and then elevated based on a single perforator (B,C). The patient is shown to have good contour and minimal donor site morbidity during follow-up (D).

musculocutaneous perforating vessels (muscle preserving) have been described.^{355–358} The sliding flap is indicated for small sacral defects, whereas the transposition flap (unilateral or bilateral) is generally appropriate for larger defects because it has a greater range of coverage. For extensive pressure sores, the gluteal thigh flap has also been useful.^{319,320,359,360}

More recently, the superior gluteal artery perforator flap has been used for the treatment of sacral pressure ulcers.³⁶¹ It affords the same skin as the gluteus maximus myocutaneous flap with the advantage that the muscle is completely spared and the pedicle length significantly increased. This is a particularly attractive alternative in the ambulatory patient.

Three distant muscles used in the reconstruction of pressure sores are the tensor fascia lata, gracilis, and the hamstrings. The tensor fascia lata (TFL) is a type I muscle that is useful for reconstructing trochanteric pressure sores.^{285,357,362} It is also a reliable alternative flap for ischial defects because of the following advantages: there is relatively low donor site morbidity, especially in an ambulatory patient; the flap provides vascularized, durable fascia; and the flap can provide sensibility in certain instances.

Several investigators have described the use of the innervated TFL flap, based on the lateral femoral cutaneous nerve (L2–L3), for reconstruction of ischial defects. They

have reported successful restoration of protective sensibility without recurrence of pressure ulceration in paraplegic patients with lesions below the L3 level.^{284,363,364}

The major disadvantage of the TFL flap is its relative thinness, a problem for the deeper pressure sore. In 1981, Schefflan described a technique to increase the bulk of the TFL flap. By de-epithelializing the distal aspect of the flap and folding the inferior portion of the flap underneath, part of the flap gains bulk. Used as a “sandwich”, the modified flap can usually fill the deeper defect.³⁶⁵ Modifications in the design of the TFL flap have been described in an attempt to minimize the donor site morbidity. Problems such as dog-ears, excessive tension at wound closure, skin necrosis at certain wound margins, and the need for skin grafts have prompted techniques such as the use of a bilobed TFL flap³⁶⁶ and the V–Y retroposition TFL flap.^{367,368} These modifications appear to facilitate donor closure in certain instances.

The gracilis is a type II muscle, first described in 1972 by Orticochea for use as a musculocutaneous flap.³⁶⁹ In the treatment of pressure sores, the gracilis is used primarily to repair the ischial defect.^{370,371} Use of the gracilis does not preclude the future use of the gluteus maximus or the posterior thigh flap if the ulcer recurs. The muscle can be elevated with the patient prone, but the distal muscle should be located before

Fig. 22.75 Gracilis flap. Arc of rotation to the perineum.

the skin island is incised, in order to ensure the correct localization of the skin overlying the muscle (Figs. 22.75 & 22.76).

The gluteus maximus muscle (type III) is well situated for coverage of both sacral and ischial pressure sores. There are a number of modifications for its design and use for both ischial and sacral pressure sores. In general, it is preferable to use segmental transposition, reserving the superior half of the muscle based on the superior gluteal artery and associated venae comitantes for the sacral sore and the inferior half based on the inferior gluteal artery and associated venae comitantes for the ischial sore.

For the sacral sore, the cutaneous territory of the superior half of the muscle may be used as a V-Y advancement flap, or the skin island may be designed distally (near the muscle insertion) for use as a transposition flap or proximally (near the muscle origin) in V-Y advancement flap. For V-Y advancement flap, the superior half of the muscle's origin and insertion is divided so the composite of muscle plus the overlying soft tissue will cover the debridement site of the sacral decubitus. Although perforating vessels will allow bilateral V-Y advancement of the skin island with release of the muscle, adequate well-vascularized soft tissue and muscle are required to provide a long-lasting stable coverage over the sacrum (Figs. 22.77 & 22.78). When it is used as a transposition flap, the skin island and underlying muscle are transferred 180° to provide sacral coverage. It is not necessary to divide the superior muscle origin, although partial to complete release of the origin allows easier flap inset over the sacrum. As already mentioned, the SGAP flap has emerged as a useful alternative to the musculocutaneous flap.

The inferior half of the gluteus maximus is ideal for ischial sore coverage. The skin island is designed near the muscle

Fig. 22.76 (A–C) Gracilis musculocutaneous flap for ischial pressure sore coverage.

Fig. 22.77 Gluteus maximus–gluteal thigh flap. (A) V–Y segmental muscle advancement (superior half of gluteus maximus muscle). Flap advancement for sacral coverage. (B) V–Y segmental muscle advancement (inferior half of gluteus maximus muscle). Flap advancement for sacral coverage.

insertion. After splitting of the muscle, the muscle and overlying skin island are easily rotated 90° to the ischial defect. The condensed bulk of the muscle and its specific cutaneous territory provide stable coverage at the ischial site of reconstruction (Fig. 22.79; see also Fig. 22.9).

The hamstrings, consisting of the biceps femoris, semimembranosus and semitendinosus, are a group of muscles of

the posterior thigh. These muscles originate from the ischial tuberosity, although the biceps femoris also has a short head originating from the linea aspera of the femur. As a group, these muscles are useful in the reconstruction of ischial pressure sores. Used as a transposition flap, depending on the size of the defect, one or more of the hamstring muscles can provide ischial coverage. Hurteau *et al.* described V–Y advancement of the hamstring musculocutaneous flap for reliable coverage of the ischial pressure sore.³⁷² A triangular island of skin overlying the hamstring muscles is designed with the base of the triangle at the inferior margin of the ischial defect. The hamstring muscles are divided distal to the skin island, and the entire muscle group is mobilized superiorly. The origins of the hamstring muscles are detached from the ischium, thus enabling further advancement, and the flap is sutured into place. Long-term results reveal stable coverage of ischial pressure sores.³⁷³

The standard of muscle or musculocutaneous flaps to reconstruct the sores of the pelvic region is now being challenged by application of perforator or fasciocutaneous flaps.^{58,63,361,374–378} The use of perforator flaps for this region preserves the muscle function as it is spared during elevation, avoids a midline scar on the mid sacrum which can frequently break when using V–Y flaps, and enables the reconstruction of recurrent pressure sores as there are multiple perforators around the defect. Fig. 22.80 shows the angiosome of the buttock and the potential perforator flaps which can be used in this region.³⁷⁸

The GAP flap is based on either superior or inferior gluteal artery perforators. Using a hand-held Doppler or CT angiogram, one can identify potential perforators around the sacral defect (Fig. 22.81A). After the initial design of the flap based on the perforator, an incision should be made on one edge. Exploration for the perforator to the skin is performed either by a subfascial or superfascial approach. If there is no adequate perforator, one can always revert to using the flap as a simple rotation flap, hence the one-edge incision (Fig. 22.81B). After identifying the perforator, the final design should be made to completely cover the defect. Incision is then made for the rest of the margin and the perforator dissected. Once adequate length is secured, the skin or the fasciocutaneous flap based on the perforator can be easily rotated as a propeller to cover the defect and close the donor site primarily (Fig. 22.81C). If a single flap is not enough to cover the defect while achieving primary closure of the donor site, multiple flaps can be used to close the defect as well as achieve primary closure of the donor site. Similar approaches can be made for the lumbar artery perforator (LAP), parasacral artery perforator (PSAP), and lateral intercostal artery perforator (LICAP) flaps based on their perforator and the site of the defect.

The adductor perforator flap can be used as an island flap to cover a perineal defect or ischial sores. Due to its location, this perforator is frequently spared from previous surgeries and injuries. The cutaneous perforator of the adductor magnus muscle could be reliably found 8 cm distal to the groin crease and 2 cm posterior to the posterior border of the gracilis muscle. The pedicle length can be long as 8–9 cm, making it easy to reach the ischial sores.^{58,376} This flap can be bulky due to the excessive subcutaneous fat but can be debulked to fit the defect.

The posterior thigh, like the anterior, lateral and medial thigh, possesses rich perforators. The largest skin territory of

Fig. 22.78 (A–E) Gluteus maximus musculocutaneous flap for treatment of a sacral pressure sore.

the posterior thigh comes from the profunda femoris artery, especially the first and second perforating arteries out of the four.^{58,378–380} Any of the perforators can be potentially used as a regional flap to cover the trochanteric and ischial defects. These flaps are evolved from the fasciocutaneous flaps of the posterior thigh.^{320,359,381,382}

Microsurgical application of flaps

Basically all local flaps can be elevated on a pedicle as a free flap. The technique of microsurgery is critical along with the steps involved during the preoperative, intraoperative and postoperative period. These critical steps will be reviewed in other chapters. Most of the muscle and musculocutaneous flaps have been covered in the regional flap section. In this section, we will briefly review common perforator flaps that are used as free flaps.

Free perforator flaps

Anterolateral thigh (ALT)

The ALT flap remains as one of the most commonly used perforator flaps for reconstruction. The perforator is found in a relatively constant region and the pedicle can be long when harvested with the source vessel. It also can be used as a compound flap with the vastus lateralis muscle and the deep fascia can be used to reconstruct the tendon defects. It is widely used for head and neck reconstruction and extremity reconstruction.

A line is drawn between the anterior superior iliac spine and superior lateral border of the patella on the donor thigh. The perforator branches are identified with Doppler near the midpoint of this line. According to our clinical experience, about 90% of perforators are found within 3 cm diameter drawn at the midpoint of the line (Fig. 22.82).^{67,383–385} The skin

Fig. 22.79 (A–E) Inferior half of the gluteus maximus musculocutaneous flap for ischial coverage.

Fig. 22.80 Angiosome of the buttock and the potential perforator flaps which can be used in this region. Key: Orange, lumbar; top blue, superior gluteal; top green, lateral sacral; top purple, internal pudendal; yellow, inferior gluteal; lateral green, lateral circumflex femoral; lower blue, adductor; aqua, profunda; lower purple, source vessels. (Image from Pan WR, Taylor GI. The angiosomes of the thigh and buttock. *Plast Reconstr Surg.* 2009;123:236–249.)

flap is designed to include the perforator and is then elevated from the medial border of the flap. The incision is made through the deep fascia when elevated subfascially and raised until the intermuscular septum between the rectus femoris and vastus lateralis muscle is reached. At that point, the descending branch of the lateral femoral circumflex is explored along with the perforator to the skin flap (Fig. 22.83). The

pedicle length can be up to 20 cm, with maximal dimensions up to 40×20 cm.^{67,386} There have been some reports of variants where the dominant perforator to the ALT flap may originate from the transverse, oblique and ascending branch of the lateral circumflex femoral artery.³⁸⁷ Thus, a free-style elevation approach to accommodate these variations may be warranted.²⁷ The ALT flap is also an excellent local flap where it

Fig. 22.81 (A) A patient with a pressure sore. After identifying a perforator near the defect, in this case an inferior gluteal artery perforator, the rest of the flap is designed based on the free-style principle and then rotated to cover the defect (B,C).

Fig. 22.82 A line is drawn between the anterior superior iliac spine and superior lateral border of the patella on the donor thigh. The perforator branches are identified with Doppler near the midpoint of this line. According to our clinical experience, about 90% of perforators are found within 3 cm diameter drawn at the midpoint of the line.

can reach the lower abdomen, pelvis, perineum and the knee by a reverse flow pattern.³⁸⁸ The flap can be harvested either as a perforator flap which includes only the perforator branch to the skin or as combined flap including the vastus lateralis muscle based on the descending branch of the lateral femoral circumflex system. The skin paddle can be defatted to about 5–8 mm thickness. The motor branch of the femoral nerve running medial to the descending branch of the lateral circumflex femoral artery should be preserved. To elevate as a sensate flap, a branch of the lateral femoral cutaneous nerve should be included. The donor site can be primarily closed depending on the laxity of the skin.

Deep inferior epigastric artery perforator (DIEAP) flap

The DIEAP flap evolved from the abdominal flaps as a free flap by Holmstrom and the pedicled flap by Hartrampf *et al.*^{223,389} Koshima and Soeda reported the first clinical use of the lower abdominal skin and fatty tissue for breast reconstruction without sacrificing rectus muscle and, since then, the use of perforator flaps for autologous breast reconstruction

Fig. 22.83 Descending branch of the lateral femoral circumflex artery is explored along with the perforator to the skin flap.

has developed in an effort to perform a safe, reliable, reproducible reconstruction with low donor-site morbidity.^{53,55,56,64}

The DIEAP flap is now one of the first-line choices for autologous breast reconstruction. The deep inferior epigastric artery (DIEA) arises from the terminal aspect of the external iliac artery deep to the inguinal ligament then ascends from the lateral aspect of the rectus abdominis muscle toward the umbilicus. It ascends between the transversalis fascia and the peritoneum before penetrating the rectus abdominis muscle. The artery enters the middle third of the muscle most frequently (78%), with the lower (17%) and upper third (5%) less frequently.³⁹⁰ After penetrating the muscle, it gives off an average of five (plus or minus two) perforators supplying the skin. Most of the perforating vessels are found within 2 cm cranial and 6 cm caudal and between 1 and 6 cm around the lateral aspect of the umbilicus.^{58,391,392} The lateral perforators may be larger and easier to dissect, but the midline perforators supply better blood flow to zone III and to zone IV.

Preoperative planning consists of the flap design in which the proposed skin island should be centered over the identified perforators. Hand-held Doppler can be used to identify the perforators assisting the flap design. CT angiograms may help to choose the perforator with the best diameter and the least dissection of the muscular segment (Fig. 22.84).

The incisions are carried down to the abdominal fascia. Scarpa's fascia is carefully maintained, and beveling is performed at the lateral aspects and at the level below Scarpa's fascia only. Using electrocautery, the flap may quickly be raised at the suprafascial level to the lateral border of the anterior rectus fascia. When a perforator is encountered, the caliber and location of the vessels are assessed and if possible should be maintained until the largest perforator can be selected (Fig. 22.85).^{56,62} Then the dissection continues through the anterior rectus fascia and the rectus muscle reaching the source vessel (Fig. 22.86). Efforts should be made to minimize muscle and nerve injury if possible. Based on a single perforator, although this may vary between individuals, the flap dimension can reach 30–45 cm in width and 11–16 cm in

Fig. 22.84 CT angiograms may help to choose the perforator with the best diameter and the least dissection of the muscular segment.

Fig. 22.85 When a perforator is encountered, the caliber and location of the vessels are assessed and if possible should be maintained until the largest perforator can be selected.

Fig. 22.86 The dissection continues through the anterior rectus fascia and the rectus muscle reaching the source vessel.

height.³⁹³ The donor site can be primarily closed depending on the laxity of the skin.

Thoracodorsal artery perforator (TDAP) flap

One of the most popular muscle flaps has been the latissimus dorsi muscle flap due to its constant vascular anatomy, big bulk of muscle and the ability to be harvested with a skin paddle. The same anatomy applies to the TDAP flap but without the need to sacrifice the muscle, thereby minimizing donor site morbidity and making it one of the workhorse perforator flaps.^{58,394} The flap can be harvested horizontally, longitudinally and in a bilobed shape but the dimension of the flap may be limited by the need for primary closure. This flap is commonly used for reconstruction of soft tissue.

The flap can be harvested in a supine position with the shoulder slightly supported by a pillow and the arm fixed in 90° abduction but the lateral decubitus position allows the flap to be harvested easily. Marking the anterior border of the latissimus dorsi muscle increases the possibility to include all

Fig. 22.87 Marking the anterior border of the latissimus dorsi muscle increases the possibility of including all perforators from this region. One can also use the Doppler to mark the perforators. Incision begins with the anteroinferior border of the skin paddle allowing identification of the anterior border of the latissimus dorsi muscle and adjustment of the flap design accordingly to place the anterior margin of the skin paddle in front of the anterior border.

perforators from this region. One can also use the Doppler to mark the perforators. Incision begins with the anteroinferior border of the skin paddle allowing identification of the anterior border of the latissimus dorsi muscle and adjustment of the flap design accordingly to place the anterior margin of the skin paddle in front of the anterior border. The main perforators overlies in the course of the descending branch of the thoracodorsal artery.³⁹⁵ After the perforator with the largest caliber and pulse, one can dissect the muscle toward the source vessel (Fig. 22.87). Pedicle length can be obtained up to 14–18 cm including the thoracodorsal vessels and skin dimensions can be up to 14×25 cm.^{58,396} The donor site can be primarily closed depending on the laxity of the skin.

Complications

Complications with the use of flaps fall into three categories: judgment, technique, and patient management. The most

common complications include seroma, hematoma, superficial skin necrosis, wound separation, inadequate coverage of the defect, infection, and partial or complete loss of the flap. By analyzing these complications in relation to judgment, technique, and patient management, the surgeon should be able to understand the cause of each complication in order to prevent subsequent complications.

Errors in surgical judgment are usually due to: inadequate preparation, inadequate flap design, or inadequate knowledge of anatomy.

Inadequate preparation is characterized by proceeding with a reconstructive procedure without having sufficient resources to perform the operation. For example, a surgeon may be asked to evaluate an elderly patient who has an extensive nonhealing ulcer involving the distal third of the leg. The surgeon recommends microvascular transplantation of a muscle flap, yet foregoes a preoperative arteriogram even though the patient has significant risk factors for peripheral vascular disease. Intraoperatively, adequate recipient vessels cannot be found and the flap is therefore aborted. This underscores the importance of preoperative preparation, especially if the diagnostic study directly impacts the surgical procedure planned.

Inadequate flap design is usually due to the surgeon's failure to account for every aspect of the surgical defect. The flap should not be designed and elevated prior to debridement of the wound. This may result in a significantly larger wound and an inadequately small flap. The flap should only be designed and elevated after the defect is completely debrided.

Inadequate knowledge of surgical anatomy may result in damage to the vascular pedicle during dissection, which can lead to failure of the flap. In addition to directly injuring the vascular pedicle, the surgeon can indirectly injure a pedicle by using a flap whose vascular pedicle is within the zone of injury, as in defects involving infection and radiation necrosis. Vascular pedicles within this environment may be compromised. For example, in a distally based flap, the minor pedicle is usually close to the defect and may be affected by the underlying cause of the defect. This is one reason that a distally based flap is less reliable than the muscle flap that is based on its dominant, major, or segmental secondary vascular pedicles. Through an appreciation of these subtle anatomic differences, proper flap selection and safe flap transposition can be achieved. It is imperative that the surgeon understand the precise anatomy of the muscle and musculocutaneous flap and the relationship to its vascular pedicle(s).

Surgical technique directly affects the outcome of any procedure. The handling of tissue, particularly vascular pedicles, is of utmost importance to the success of the flap. Vessels can be injured at any stage of the operation and are subject to spasm, kinking, shearing, and twisting. One preventative

measure is the placement of temporary sutures between the skin of the flap and the underlying muscle or fascia to prevent shearing of the musculocutaneous perforating vessels. Other techniques include avoidance of skeletonizing the vascular pedicle unless absolutely necessary to avoid spasm and injury. Lastly, in flaps that are tunneled beneath skin bridges, it is important to avoid a tourniquet effect produced by the potentially constrictive skin bridge.

Ultimate flap loss can be due to intrinsic or extrinsic reasons. Flap loss due to intrinsic reasons is largely caused by inadequate blood supply, which is the most common reason of flap compromise. Flap compromise due to extrinsic circumstances include infection, hypotension, and vasoconstricting agents such as pressors. Compression or tension on the flap due to hematoma is another extrinsic cause of flap compromise. Exploration of the flap should be expeditious when failure is suspected.

Donor site complications include fluid collections due to dead space (seroma, hematoma), wound separation, infection and injury to adjacent structures during flap harvest.

Errors in patient management are a common cause of postoperative complications. For patients undergoing flap surgery, the most common errors of management include: (1) inadequate attention to the patient's underlying medical conditions; (2) inadequate assessment or management of intravascular volume status; and (3) inadequate surveillance of flap viability and perfusion.

The safety and reliability of muscle and musculocutaneous flaps has been repeatedly demonstrated. Such successes now encourage surgeons to choose a more complex procedure than a simple one, especially if form and function can be improved. For example, in the reconstruction of a defect involving the lower leg, the soleus and gastrocnemius provide reliable and safe closure. However, the aesthetic and functional results may be unacceptable to certain patients. In these patients, a more sophisticated technique such as perforator-based propeller flaps, and perforator flaps with microsurgery approach may be appropriate and become the procedure of choice according to the reconstructive elevator concept.

Microvascular tissue transplantation is clearly indicated as the procedure of choice for certain defects. In fact, the use of microvascular free tissue transfer to reconstruct head and neck defects has revolutionized the field and has allowed both functional and aesthetically pleasing results for large extirpative defects. The term "microsurgery" has evolved to the concept of supermicrosurgery and the variety and concept of flaps are evolving from musculocutaneous to perforator flaps. Although the complexity of reconstruction and the approach are continuously evolving, the basic principle of flap selection and application remains the same: The quality of the result is far greater than the risk involved.

BOX 23.1 Selected abbreviations

5HT ₂	serotonin
Ad.VEGF ₁₆₅	adenoviral vectors encoding the cDNA of VEGF ₁₆₅
ATP	adenosine triphosphate
EDCF ₅	endothelium-derived contracting factors
EDRF _s	endothelium-derived relaxing factors
ET-1	endothelin-1
FGF	fibroblast growth factor
MPO	myeloperoxidase
mPTP	mitochondrial permeability transitional pores
NADPH	neutrophilic nicotinamide adenine diphosphate
NE	norepinephrine
NHE-1	Na ⁺ /H ⁺ exchange isoform-1
NO	nitric oxide
O ₂ ⁻	superoxide radicals
•OH	cytotoxic hydroxyl radical
PDGF	platelet-derived growth factor
PGI ₂	prostacyclin
TRAM flaps	transverse rectus abdominis myocutaneous flaps
TXA ₂	thromboxane A ₂
VEGF	vascular endothelial growth factor

Introduction

Flaps, both pedicled and free, are routinely used to reconstruct defects resulting from injury, excision of tumors,

ulceration, or congenital malformation.¹⁻³ The clinical problem is that flap failure as a result of ischemic necrosis occurs in both pedicled and free flaps. In free flaps alone, ischemic necrosis occurs in 5–10% of patients, even in experienced hands.⁴⁻¹⁰ Flap necrosis can be partial or total.¹¹⁻¹³ Flap failure is time-consuming and costly because it requires repeated surgery and prolonged hospitalization. In the US, the additional operating room cost ranges from about \$40 000 to \$68 000 for each total free flap failure, and the additional surgeon reimbursement ranges from \$5000 to \$35 000 for each surgery.^{14,15} In addition, repeated surgery increases the incidence of donor site deformity and/or morbidity, with devastating effects on the patient. Therefore, we need to understand the pathophysiology of ischemic necrosis in pedicle and free flap surgery because this information may lead us to develop effective pharmacological therapies to prevent or salvage flap failure.

Pathophysiology of flap failure

Vasospasm and thrombosis in the pathogenesis of pedicle and free flap failure

Clinically and experimentally, ischemic necrosis occurs mainly in the distal portion of both pedicle and free flaps. The general consensus is that vasospasm and thrombosis due to surgical trauma and insufficient distal vascularity are the main pathogenic factors in pedicle and free flap failure,³ but little is known about the pathogenic mechanism. However, there are published reviews on the role of vasoactive neurohumoral substances in the local regulation of peripheral vascular tone in normal and diseased states.¹⁶⁻²¹ These articles may provide insight into the pathogenesis of vasospasm and thrombosis in flap surgery, as illustrated in Fig. 23.1. Briefly, endothelium-derived relaxing factors (EDRFs) such as prostacyclin (PGI₂) and nitric oxide (NO) cause relaxation of vascular smooth muscle and inhibit platelet aggregation.

Fig. 23.1 Vasoconstriction in surgical trauma and vascular damage in ischemia–reperfusion injury. In surgical trauma, norepinephrine is released by sympathetic nerve endings and thromboxane A_2 , leukotriene B_4 , and serotonin are released by traumatized platelets and hemoglobin by red blood cells to cause vasoconstriction. Traumatized endothelial cells also decrease synthesis of vasodilating prostacyclin and endothelium-derived relaxing factor/nitric oxide (EDRF/NO). In reperfusion of ischemic blood vessels, superoxide radicals (O_2^-) are produced by platelets and neutrophils. These free radicals can damage blood vessels.

On the other hand, endothelium-derived contracting factors (EDCFs) such as thromboxane A_2 (TXA_2), and endothelin-1 (ET-1) raise vascular tone. Under physiological conditions, a balance of vascular effects between EDCFs and EDRFs maintains adequate tissue perfusion. However, an imbalance can occur as a result of surgical trauma, as shown in Fig. 23.1. Specifically, traumatized sympathetic nerve endings release norepinephrine (NE), causing vasoconstriction and platelet aggregation. The NE released by the sympathetic nerve endings, leukotriene B_4 , serotonin ($5HT_2$) and TXA_2 released by the platelets, and the ET-1 released by the traumatized vascular endothelial cells can cause vasoconstriction and intravascular platelet aggregation, especially in the small arteries in the distal portion of the flap where the perfusion pressure is low and the concentration of these vasoconstrictive substances is high due to the downstream effect. Hemoglobin from hemolyzed red blood cells (e.g., hematoma) is also a potent vasoconstrictor. The histamine released by the mast cells changes the membrane permeability, resulting in edema formation. Furthermore, the synthesis and release of EDRFs such as PGI_2 and NO from the traumatized vascular endothelium are depressed. In addition, the rate of endothelial degradation of NE and $5HT_2$ by catechol-O-methyl transferase and monoamine oxidase, respectively, is reduced in situations of impaired endothelial function. The end result is that there are high local levels of vasoconstrictive and prothrombotic neurohumoral substances in surgical trauma and these

substances exacerbate vasospasm and promote thrombosis in flap surgery.

In reperfusion of ischemic blood vessels, superoxide radicals (O_2^-) are produced by platelets, neutrophils, and endothelial cells and these free radicals can damage vascular walls during reperfusion (see Fig. 23.1).

Xanthine dehydrogenase/xanthine oxidase enzyme system in pathogenesis of ischemia–reperfusion injury in free flap surgery

In free flap surgery, skin and muscle are subjected to warm (room-temperature) global ischemia under vascular clamp control during transfer from donor site to recipient site prior to re-anastomosis. Human muscle and skin can withstand 2–2.5 hours and 6–8 hours of warm global ischemia, respectively.^{22–26} Excessive ischemic insult can result in ischemia–reperfusion injury caused by energy depletion and formation of oxygen-derived free radicals, as shown in Fig. 23.2. During prolonged ischemia, adenosine triphosphate (ATP) in skin and muscle is catabolized stepwise to hypoxanthine, with concomitant increase in cytosolic Ca^{2+} .²⁷ At the same time, a cytosolic protease is activated by intracellular Ca^{2+} and it converts xanthine dehydrogenase to xanthine oxidase.^{28,29} During reperfusion, the xanthine oxidase generates superoxide (O_2^-) by univalent reduction of

Tissue ischemia
(ATP catabolism)

Fig. 23.2 Pathogenesis of oxygen-derived free radicals in reperfusion of ischemic tissues. AMP, adenosine monophosphate; ATP, adenosine triphosphate; $O_2^{\cdot -}$, superoxide; H_2O_2 , hydrogen peroxide; $\cdot OH$, hydroxyl radical; 1O_2 , singlet oxygen; $RO_2^{\cdot}$, peroxy radicals; $ROOH$, hydroperoxide.

molecular oxygen in the presence of hypoxanthine.³⁰ The unstable $O_2^{\cdot -}$ forms H_2O_2 spontaneously by dismutation. Furthermore, the unstable $O_2^{\cdot -}$ also interacts with H_2O_2 in the presence of a transition metal (e.g., iron) to form the most potent cytotoxic hydroxyl radical ($\cdot OH$) through the Haber-Weiss (Fenton) reaction,³¹ as shown in Fig. 23.2. There is evidence to suggest that this hypoxanthine/xanthine oxidase system is a main source of oxyradicals in ischemic rat skin and muscle.^{32,33} Furthermore, inhibition of xanthine oxidase activity by allopurinol and depletion of xanthine oxidase with a tungsten diet have been shown to attenuate the microvascular damage in rat skeletal muscle subjected to 2 hours of ischemia and 30 minutes of reperfusion.³⁴

However, there is also evidence to indicate that the hypoxanthine/xanthine oxidase system is not a main source of oxyradicals in pig and human skin and skeletal muscle. Control pig and human skin samples have been found to contain minimal xanthine oxidase activity, almost 40 times less than that of the rat, and xanthine oxidase activity did not rise during the first 8 hours of ischemia in these experiments.³⁵ In pigs, intravenous allopurinol given 60 minutes before ischemia did not protect cutaneous or musculocutaneous flaps from necrosis when subsequently subjected to 8 hours of warm ischemia and 5 days of reperfusion.³⁶ Similarly, we observed that xanthine oxidase activity in pig and human skeletal muscle was minute (<0.5 mU/g wet weight) compared with that of the rat.³⁷ In addition, we observed that 5 days of competitive xanthine oxidase inhibitor treatment (allopurinol 25 mg/kg i.v., b.i.d.) starting 2 days before ischemia or 3 days of noncompetitive xanthine oxidase inhibitor treatment (oxypurinol, 25 mg/kg, i.v., b.i.d.) starting 15 minutes before reperfusion did not attenuate pig latissimus dorsi muscle necrosis when subjected to 5 hours of ischemia and 48 hours of reperfusion.³⁷

Neutrophilic nicotinamide adenine diphosphate (NADPH) and myeloperoxidase (MPO) enzyme system in pathogenesis of ischemia/reperfusion injury in free flap surgery

There is accumulated evidence to indicate that neutrophils may play an important role in ischemia-reperfusion injury in free flap surgery. For example, it is well known that activated neutrophils produce large amounts of $O_2^{\cdot -}$ via NADPH oxidase, and these $O_2^{\cdot -}$ dismutates yield a high concentration of H_2O_2 and $\cdot OH$, causing tissue damage.³⁸ MPO, which is unique and abundant in neutrophils, catalyzes the conversion of H_2O_2 to hypochlorous acid ($HOCl$), a potent cytotoxic oxidizing agent ($H_2O_2 + Cl^- + H^+ \rightarrow HOCl + H_2O$).^{39,40} Furthermore, it was reported that treatment with monoclonal antibodies against neutrophil-endothelium adhesion molecules attenuated ischemia-reperfusion-induced skin necrosis in rabbit ears,⁴¹ rat epigastric island skin flaps,⁴² and skin and muscle in pig latissimus dorsi musculocutaneous flaps.⁴³ Treatment with monoclonal antibody against neutrophil-endothelium adhesion molecules also attenuated arteriolar vasoconstriction induced by ischemia-reperfusion injury.⁴⁴ Finally, neutrophil depletion ($\sim 95\%$) with mechlorethamine significantly reduced necrosis in pig latissimus dorsi muscle flaps subjected to 5 hours of warm ischemia and 48 hours of reperfusion.³⁷ Also, neutrophil depletion attenuated vascular injury in dog gracilis muscle subjected to 4 hours of warm ischemia and 1 hour of reperfusion.⁴⁵

Paradoxically, there are arguments against the important role of neutrophils in the pathogenesis of animal or human myocardial ischemia-reperfusion injury.⁴⁶⁻⁴⁸ Several investigators found that ischemia-reperfusion injury could be induced in neutrophil-free systems such as in cultured animal cardiomyocytes⁴⁹ and human atrial strips^{50,51} and in isolated perfused animal hearts.⁵²⁻⁵⁴ In clinical studies, free oxyradical scavengers were not effective in protecting myocardium from ischemia-reperfusion injury.^{55,56} Furthermore, although monoclonal antibody to intercellular adhesion molecule-1 and anti-CD18 antibodies were effective in protecting myocardium against ischemia-reperfusion in laboratory animals,^{57,58} clinical trials with these agents yielded negative results.⁵⁹⁻⁶¹ More recently, we observed that ischemia-reperfusion injury was also induced in human rectus abdominis muscle strips cultured in neutrophil-free buffer.⁶² There is the possibility of species difference in the role of neutrophils in the pathogenesis of ischemia-reperfusion injury. Therefore, it is important to clarify the causal role of neutrophils in ischemia-reperfusion injury in human skin and skeletal muscle.

Intracellular Ca^{2+} overload in pathogenesis of ischemia-reperfusion injury in free flap failure

Recently, experimental evidence has shown that intracellular Ca^{2+} overload plays a key role in causing cell death during myocardial reperfusion.⁶³ The pathogenic mechanism is summarized in Fig. 23.3. It appears that, in sustained ischemia, mitochondrial ATP synthesis ceases and glycolysis ensues, resulting in a net breakdown of ATP and an accumulation of

Fig. 23.3 Proposed role of intracellular Ca²⁺ overload in the pathogenesis of ischemia-reperfusion injury. ATP, adenosine triphosphate.

lactate and intracellular H⁺,⁶⁴ causing intracellular acidosis. This build-up of intracellular H⁺ activates the Na⁺/H⁺ exchanger isoform-1 (NHE-1) antiporter, resulting in extrusion of H⁺ and accumulation of intracellular Na⁺ to restore intracellular pH. There is a further increase in intracellular Na⁺ accumulation because Na⁺ extrusion is limited by inactivation of the energy-dependent Na⁺-K⁺-ATPase pump.^{65,66} Elevation of intracellular Na⁺ concentration causes an increase in intracellular Ca²⁺ by activation of the Na⁺/Ca²⁺ exchanger causing Ca²⁺ influx.^{65,67–70} If these events continue, the cytosolic Ca²⁺ will be overloaded, and significant uptake of Ca²⁺ from the cytosol to the mitochondria will occur, resulting in mitochondrial Ca²⁺ overload⁷¹ which causes depolarization of mitochondria and impairs ATP synthesis, resulting in cell necrosis⁵² (see Fig. 23.3). However, the NHE-1 may be inhibited⁷² if the extracellular acidosis is more pronounced than the intracellular acidosis after a prolonged period of ischemia.⁷³ At reperfusion, the rapid washout of the extracellular H⁺ reactivates the NHE-1, resulting in further extrusion of intracellular H⁺, and further accumulation of intracellular Na⁺, causing further cytosolic Ca²⁺ overload through Na⁺/Ca²⁺ exchange.^{67,74} Again, cytosolic Ca²⁺ overload causes mitochondrial Ca²⁺ overload, impairing ATP synthesis and resulting in cell

death.^{52,71} Recently, we have seen evidence to suggest that mitochondrial Ca²⁺ overload plays an important role in ischemia-reperfusion in skeletal muscle and this will be discussed later, along with the therapeutic treatment aimed at preventing mitochondrial Ca²⁺ overload.

Pathogenesis of no-reflow phenomenon in free flap surgery

May *et al.* used rabbit island epigastric skin free flaps to study the pathogenesis of the no-reflow phenomenon in free flap surgery.⁷⁵ They observed that ischemia induced swelling of the endothelial and parenchymal cell, narrowing of the capillary lumen, which led to intravascular aggregation of blood cells, and leakage of intravascular fluid into the interstitial space to form edema. This pathology increased with the increase in length of ischemic time from 1 to 8 hours and the obstruction of blood flow reached a point of irreversibility after 12 hours of ischemia, leading to no reflow and ultimate death of the flap. Three pathogenic mechanisms have been suggested to play a central role in the development of the no-reflow phenomenon in the skeletal muscle of laboratory animals: (1) oxygen-derived free radicals causing damage in the endothelial and parenchymal cells; (2) this cell membrane damage allowing Ca²⁺ influx, resulting in intracellular overload; and (3) change in arachidonic acid metabolism resulting in synthesis of less vasodilating and antithrombotic PGI₂ by the endothelium and increased synthesis of vasoconstricting and thrombotic TXA₂ by platelets.⁷⁶

Surgical manipulation for augmentation of pedicle flap viability

Clinically and experimentally, there are several surgical manipulations which have proved effective in augmenting flap viability.

Flap design in augmentation of pedicle flap viability

One of the misleading principles in plastic surgery is that the viable length of a skin flap depends on the width of the pedicle. Milton was the first to disprove this principle.^{1,77–79} Using a random-pattern skin flap model in the pig, it was demonstrated that the ultimate surviving length of a pedicle flap is determined by the balance between perfusion pressure and vascular resistance. Increasing the width of pedicle flaps merely adds additional vessels of the same type and the same perfusion pressure and thus cannot increase the length of flap viability (Fig. 23.4). However, in other locations of the body, increasing the width of the pedicle may increase the chance of including a large artery. Therefore, one of the surgical manipulations to augment flap viability is the conversion of a random-pattern skin flap to an arterialized or axial skin flap by incorporating a direct artery or a larger perforator.

Surgical delay in augmentation of pedicle flap viability

Surgical delay and vascular delay are proven techniques for augmenting flap viability in human patients,^{80–84} as well as in

Fig. 23.4 The length-to-width ratio concept in flap design.

laboratory animals such as mice, rats, rabbits, and pigs.^{85–98} It takes two to three stages in surgical delay of pedicle skin flaps in order to augment flap viability. Specifically, a skin flap is mapped out on the donor site and incised on its two longitudinal sides. The flap is then undermined to form a bipedicle flap and is sutured back to the donor site. Two to three weeks after construction of the bipedicle flap, the third side (distal end) is cut in one or two stages at 2–3 days apart. At the end of this stage, a single pedicle flap is completely raised and the distal portion of the flap is moved to the recipient site for wound coverage without skin necrosis.^{1,99} In studies with pig random-pattern skin flaps, we and other investigators showed that surgical delay increased skin flap capillary blood flow between 2 and 7 days of delay.^{100,101} This increase in capillary blood flow was mainly in the distal random portion of the delayed skin flaps.¹⁰¹

Vascular delay in augmentation of pedicle flap viability

In mice, rats, and rabbits, vascular delay for augmenting blood flow and viability in the distal portion of latissimus dorsi muscle flaps was achieved by dividing distal perforating arteries at 1–2 weeks prior to raising the muscle flaps.^{93,95,96} This phenomenon was also achieved in transverse rectus abdominis myocutaneous (TRAM) flaps in laboratory animals as well as in human patients. Division of perforators or one or two dominant arteries that supply blood to the rectus abdominis muscle 2–3 weeks before flap surgery significantly augmented viability in TRAM flaps in rats^{91,92,94,97} and augmented skin and muscle blood flow and viability in TRAM flaps in pigs.^{91,92} In human patients, ligation of the deep inferior epigastric arteries 2–4 weeks before flap surgery augmented skin blood supply^{83,102,103} and viability in TRAM flaps.^{80–82,84}

Surgical and vascular delay have been proven clinically effective in augmenting flap viability, but these surgical procedures are costly and time-consuming. They require at least one additional surgical step done under general anesthesia. Vascular delay by embolization does not require general anesthesia, but it requires local anesthesia and catheterization performed in the interventional radiology department.¹⁰⁴ Recently, “recharging” of the TRAM flap has been described as an alternative technique to augment flap perfusion.¹⁰⁵ The evolution of microsurgery saw the development of free flaps. The idea was to improve flap blood flow and viability. TRAM

free flaps are a good example as the free TRAM is perfused by the more dominant deep inferior epigastric pedicle rather than the less dominant superior epigastric vessels that supply the pedicled TRAM.^{105–110} However, in some situations free flap surgery is not available. It requires specialized microsurgical staff and equipment and long operating room time. Furthermore, free flap surgery is not without morbidity and flap ischemic necrosis due to thrombosis and vasospasm occurs in 5–10% of patients.^{4–10,110} Therefore, there is the need to understand the mechanism of the surgical delay phenomenon through research to identify pharmacological strategies to prevent/treat ischemic necrosis.

Mechanism of surgical delay in augmentation of pedicle flap viability

Many investigators have studied the surgical delay phenomenon in laboratory animals in order to gain insight into the pathogenesis and pharmacological treatment for skin flap ischemic necrosis. Several hypotheses have emerged from these studies.

Surgical delay procedure reduces arteriovenous (AV) shunt flow

Reinisch reported good correlation between postoperative fluorescein staining and the eventual skin viability in pig skin flaps. He detected warm skin temperature beyond the fluorescein dye marker in the distal portion of the pig skin flap.¹¹¹ He also demonstrated ⁵¹Cr-labeled red blood cells and technetium and ⁸⁵Sr-microsphere (15 μm) activity beyond the fluorescein dye staining in acute pig skin flaps.¹¹¹ Taken together, he hypothesized that, in acute skin flap surgery, distal ischemic necrosis was caused by opening of AV shunt flow as a result of sympathetic denervation. He speculated that shunt flow occurred throughout the skin flap and the flow in the proximal areas is sufficient to supply both the AV and capillary (nutrient) blood flow, but the shunting became lethal in the distal areas of the skin flap where the total blood flow was low. In surgical delay, the bipedicle skin flap provided sufficient blood supply during the early period of sympathetic denervation and opening of AV shunts. Pearl presented data from rat abdominal arterial skin flaps, which supported Reinisch’s hypothesis, and also suggested that surgical delay allowed the skin flap to recover from its hyperadrenergic state before converting the bipedicle to single-pedicle skin flaps.¹¹² However, these observations were not supported by other investigators. For example, Prather *et al.*, using various laboratory techniques (fluorescein dye test, xenon clearance, angiography, ⁵¹Cr-tagged red blood cells and thermometry), failed to detect any evidence of vascular perfusion in the non-fluorescein distal portion of acute axial pattern skin flaps in the pig.¹¹³ In contrast to Palmer’s findings¹¹⁴ in rat dorsal skin flaps, Cutting *et al.*^{115,116} did not observe persistent adrenergic denervation in delayed bipedicle skin flaps. Later, Guba used 15 μm and 50 μm radioactive microspheres to measure capillary (nutrient) and total blood flow, respectively, and to calculate AV shunt flow in bipedicle axial pattern pig skin flaps. Both capillary and AV shunt flow increased between 2 and 7 days of delay in pig bipedicle skin flaps, but this increase in capillary blood flow in delayed bipedicle skin flaps was not the result of a decrease in AV shunt flow.¹⁰⁰

Subsequently, using 15 μm and 50 μm radioactive microspheres as well as fluorescein dye, Kerrigan¹¹⁷ found no evidence of AV shunt flow in the distal portion of acute random and arterial pig skin flaps destined to necrose, as indicated by lack of fluorescein penetration. Finally, using a similar radioactive microsphere technique, Pang *et al.* demonstrated that AV shunts played no important role in the pathogenesis of distal ischemic necrosis in random-pattern skin flaps in the pig and augmenting distal skin viability by surgical delay did not rely on closing of AV shunts, but vasodilation of existing blood vessels.^{101,118} It is important to point out that there may also be species differences in the extent of AV shunt flow in the skin assessed by the radioactive microsphere technique. Specifically, our lab observed in the pig that the AV shunt flow in the control skin and in the skin of acute and delayed random-pattern skin flaps within 6 hours postoperatively was ~60% of the total blood flow.¹⁰¹ However, Sasaki and Pang¹¹⁹ observed in the rat that the AV shunt flow in abdominal island skin flaps within 6 hours postoperatively was ~10% of the total skin blood flow. More recently, Kreidstein *et al.*¹²⁰ in our laboratory observed that the AV shunt flow in isolated perfused human para-umbilical skin was ~1%. Taken together, these studies seem to indicate that AV shunt flow does not play an important role in the pathogenesis of distal ischemic necrosis in acute pedicle skin flaps.

Surgical delay procedure depletes vasoconstriction and prothrombotic substances in the skin flap

Local tissue content of vasoconstricting and prothrombotic substances such as NE, TXA₂, 5HT and ET-1 are known to be elevated by surgical trauma.^{3,121–135} These substances are released locally by traumatized blood cells, endothelial cells, and sympathetic nerve endings (see Fig. 23.1). These are potent vasoconstrictors in skin vasculature.^{134,136–143} There is a general consensus that vasospasm and thrombosis play an important role in the pathogenesis of ischemic necrosis in acute skin flaps and the surgical delay procedure reduces local production and also allows time to deplete the vasoconstricting and prothrombotic substances before converting the bipedicle flap to single-pedicle flaps. In the past, research in skin flap surgery was focused on the use of vasodilating and antithrombotic drugs to augment skin flap viability. So far, the outcomes of pharmacological therapy for the prevention or treatment of pedicle flap ischemic necrosis are disappointing and will be discussed later.

Surgical delay procedure induces vascular territory expansion by opening existing choke arteries

Pang *et al.* studied the capillary blood flow in delayed random-pattern pig skin flaps. We found that the capillary blood flow increased significantly within 2 days of delay and a maximum increase in skin flap capillary blood flow occurred between 2 and 3 days of delay, and remained unchanged between 4 and 14 days of delay without an increase in density of arteries (arteriogenesis) assessed by histology. This increase in capillary blood flow occurred mainly in the distal portion of the skin flap.¹⁰¹ Similar increase in capillary blood flow

Fig. 23.5 Opening of existing blood vessels (choke vessels) in the distal portion of the surgically delayed skin flap.

was also seen in vascular delay of pig TRAM flaps within 3–4 days of delay and it is unlikely that an increase in arterial density (arteriogenesis) could have occurred during this short period of time. Therefore, these investigators described this phenomenon as vascular territory expansion by recruitment (opening) of existing arteries, as illustrated in Fig. 23.5.⁹⁰ Opening of existing blood vessels was demonstrated by Taylor and colleagues in vascular delay of skin flaps in the guinea pig, rabbit, dog, pig, and human,^{144–147} and by Yang and Morris in vascular delay of rat skin flaps,^{148,149} and this phenomenon was labeled by these investigators as angiosome territory expansion by opening of existing choke blood vessels.

Surgical delay procedure induces angiogenesis

Lineaweaver *et al.* reported that vascular delay increased the viability of the skin paddle of rat TRAM flaps and this protective effect of vascular delay was associated with a significant increase in gene expression of vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (FGF) in the skin paddle of the rat TRAM flaps within 12 hours of vascular delay. These investigators speculated that these cytokines induced vasodilation and angiogenesis to augment skin paddle viability in rat TRAM flaps.¹⁵⁰ The vascular

mechanism of surgical delay is still unclear. However, it was previously reported that the angiogenesis inhibitor endostatin inhibited ischemia-induced microvascular density and viability of mouse dorsal random-pattern skin flaps.¹⁵¹ Therefore, endostatin can be used in the future to investigate the role of angiogenesis and arteriogenesis in surgical delay in skin flap surgery in laboratory animals.

Pharmacological therapy for augmentation of pedicle flap viability

As discussed previously, the surgical delay procedure is costly and time-consuming. Therefore, much research has been focused on drug therapy for augmenting blood flow and viability in pedicle flap surgery.

Drug therapy against vasoconstriction and thrombosis in pedicle flap surgery

Vasoconstricting and prothrombotic substances such as NE, TXA₂, 5HT, and ET-1 are known to be elevated in skin flap surgery as a result of surgical trauma.^{121–131,135} These are very potent vasoconstrictors.^{134,136–142} In the past, research in skin flap surgery was focused on the use of vasodilating and antithrombotic drugs to augment skin flap viability. These studies were reviewed in detail up to 1990 by various investigators and will not be discussed here.^{3,117,152,153} The categories of drugs included: α -adrenoreceptor antagonists; drugs causing depletion of catecholamine in nerve terminals; drugs preventing catecholamine release from the nerve terminal; β -adrenoreceptor agonists; direct vasodilators, calcium channel blockers, hemorrhheological drugs; vasodilating eicosanoids and their synthesis inhibitors; anti-inflammatory drugs; drugs inhibiting adherence and accumulation of neutrophils; and free radical scavengers. More recently, research in drug therapy for augmenting flap viability also focused on vasodilation,^{154–170} antithrombosis,¹⁷¹ and inhibition of neutrophil from adherence and accumulation.¹⁷² In general, the results with these vasodilating and antithrombotic drug treatments in augmenting pedicle flap viability were controversial, inconclusive, or very modest at best, compared with surgical delay. Finally, most of these studies were performed in loose-skinned laboratory animals (e.g., rats, rabbits) whose skin vasculature and anatomy are likely different from those of the human.⁷⁸ Using more clinically relevant pig pedicle skin flap models, Pang and colleagues tested several drugs, which were reported to augment rat skin flap viability by other investigators. We found that neither skin blood flow nor viability was significantly improved by the following categories of drug: glucocorticoid,¹⁷³ α -adrenoreceptor antagonists,⁸⁸ vascular smooth-muscle relaxants,^{174,175} β -adrenoreceptor agonist,¹⁷⁴ TXA₂ synthesis inhibitor,¹⁷⁴ TXA₂ receptor antagonist,¹⁷⁴ and vasodilating prostanoids.¹⁷⁶ We also found that 5HT₂ receptor antagonists augmented skin flap viability in the pig, but the beneficial effect was modest compared with surgical delay.^{174,177} In conclusion, the mechanism of surgical or vascular delay is unclear. So far, there is no effective drug therapy which can mimic surgical or vascular delay in augmenting skin flap viability.

Angiogenic cytokine protein or gene therapy for augmentation of pedicle flap viability

Angiogenic cytokines such as VEGF, FGF, and platelet-derived growth factors (PDGF) are known to induce an increase in capillary density (angiogenesis). Recently, flap research has been focused on the use of local angiogenic cytokine protein therapy to augment flap viability. For example, improved viability was observed following local subdermal injection of VEGF₁₆₅ immediately after elevation of rat dorsal random-pattern skin flaps;^{178,179} local interarterial injection of VEGF₁₆₅ immediately after raising of rat epigastric island skin flaps;^{180,181} and injection of VEGF₁₆₅ into the rectus abdominis muscle 20 days before construction of TRAM flaps in the rat.¹⁸² There is also evidence to indicate that FGF can augment skin flap viability. This has been observed following intradermal injection of FGF 30 minutes before surgery in rat dorsal random-pattern skin flaps;¹⁸³ subdermal injection of FGF immediately after surgery and at 48 hours postoperatively in rat dorsal random-pattern skin flaps;¹⁸⁴ and subdermal injection of FGF 18 days before construction of arterial skin flaps in mouse ears.¹⁸⁵ Last but not least, it was reported that local PDGF treatment mimicked the surgical delay phenomenon in augmenting latissimus dorsi muscle viability in the mouse.¹⁸⁶ So far none of these angiogenic cytokines has been tested on tight-skinned animals such as the pig. Since the angiogenic cytokines were effective in augmenting skin flap viability when given several days before or immediately after surgery, it is possible that vasodilation may play an important role in this mechanism. Khan *et al.* in our laboratory used the rat dorsal random-pattern skin flap model to study the mechanism of acute local intradermal VEGF₁₆₅.¹⁸⁷ These studies showed that subdermal injection of VEGF₁₆₅ at the time of surgery effectively attenuated pedicle skin flap ischemic necrosis in a dose-dependent manner, mainly by inducing the synthesis/release of the vaso-relaxing factor NO. The mechanism by which VEGF₁₆₅ augmented skin flap viability appeared to depend on the vasodilator effect of VEGF₁₆₅ in the early stage (within 6 hours) after surgery, followed by the angiogenic effect (i.e., increase in capillary density) of VEGF₁₆₅ in the later stage after surgery. It is important to point out that VEGF₁₆₅ is a potent vasodilator in skin vasculature. Specifically, we observed that VEGF₁₆₅ was seven times more potent than acetylcholine in inducing skin vasodilation in isolated perfused pig island buttock skin flaps.¹⁸⁸

The biological half-life of VEGF₁₆₅ is 30–45 minutes in normoxic and 6–8 hours in hypoxic conditions.¹⁸⁹ It is possible that the effectiveness of VEGF₁₆₅ protein therapy is limited by its short half-life and VEGF₁₆₅ gene therapy may be the key to providing a steady release of VEGF₁₆₅ perioperatively.¹⁹⁰ Specifically, local intradermal or subcutaneous injection of liposomal or adenoviral vectors encoding the cDNA of VEGF₁₆₅ (Ad.VEGF₁₆₅) given at 0.5, 2, 3, 7, or 14 days before surgery was shown to augment skin flap viability in the rat.^{191–194} Local subcutaneous injection of VEGF₁₆₅ plasmid DNA 7 days preoperatively also increased skin viability in rat musculocutaneous (TRAM) flaps.¹⁹⁵ Of interest is the observation that the number of capillaries and arterioles were significantly increased in the skin of rat musculocutaneous (TRAM) flaps when Ad.VEGF₁₆₅ was injected subcutaneously 14 days before surgery.¹⁹⁶ However, it is important to point out that review of the data in the literature to date indicates that the efficacy

of rat dorsal skin flap viability augmentation was similar between VEGF₁₆₅ protein and gene therapy, and the skin flap viability was about 15–20% lower than that of surgical delay.^{187,197} Therefore, more than VEGF₁₆₅ is required to mimic surgical delay in augmenting flap viability.

Pharmacological therapy for augmentation of free flap viability

Vasospasm, thrombosis, and ischemia–reperfusion injury are the main causes of free flap failure. At the present time, there are relatively safe drugs which are used clinically to prevent or treat vasospasm and thrombosis in flap surgery. However, drug therapy for ischemia–reperfusion injury remains a subject of animal research.

Drug therapy for prevention of vasospasm and thrombosis in free flap surgery

Drug therapy is used by some surgeons to prevent or treat anastomotic vasospasm and thrombosis in free flap surgery. These drugs can be classified into three categories and their dosage, efficacy, and treatment guidelines have been reviewed.^{198–200}

Anticoagulant agents

Heparin, aspirin, and dextran are the three common anticoagulants used in microsurgery, but their efficacy is unclear. For example, it has been reported that intravenous heparin treatment reduced the incidence of anastomotic thrombosis when given before the restoration of blood flow in the rabbit.²⁰¹ Subsequently, results from two clinical studies in free flap surgery indicated that low dosage of intraoperative heparin treatment (3000 or 5000 units intravenously) did not increase the rate of hematoma formation or intraoperative bleeding. However, these low doses of heparin treatment also did not have any significant effect on the prevention of microvascular thrombosis.^{202,203} Obviously, a higher systemic dose of heparin is required. Some surgeons recommend an intraoperative bolus injection of 100–150 units/kg of intravenous heparin before cross-clamping and a supplement injection of 50 units/kg of heparin every 45–50 minutes until re-establishment of blood flow after anastomosis.²⁰⁴ However, this is not common practice. More clinical research is required to identify an effective dose of heparin for the prevention of anastomotic thrombosis without hematoma formation in free flap surgery.

It was observed in the rabbit that a low dose of aspirin (10 mg/kg) caused an antithrombotic effect because it reduced TXA₂ (vasoconstrictor) formation in the platelet to a greater extent than PGI₂ (vasodilator) formation in the endothelium.²⁰⁵ Low doses of aspirin were also observed to inhibit anastomotic thrombosis and improve the microcirculation in the rat.²⁰⁶ In humans, lower doses of aspirin (40–325 mg) were observed to inhibit platelet cyclo-oxygenation production of TXA₂ with minimal inhibition of endothelium-derived production of PGI₂.^{207–209} However, more than 24 hours are required to achieve maximal cyclo-oxygenation inhibition.^{207,210} It was also reported that a low oral dose of aspirin (325 mg/day) did not cause postoperative hematoma formation in

clinical free flaps.²¹¹ Furthermore, there is clinical evidence to indicate that a low dose of aspirin is effective in preventing coronary graft occlusion given preoperatively or within 24 hours of surgery.^{212,213}

The low-molecular-weight dextran 40 (MW 40000) and dextran 70 (MW 70000) are known to have blood volume expansion and antithrombogenic effects in humans.²¹³ Dextran 40 is the most popular dextran used to decrease platelet aggregation and to improve blood flow in free flap surgery. The effective doses have been reviewed elsewhere.²⁰⁰ However, dextran 40 also has undesirable side effects such as anaphylaxis, pulmonary and cerebral edema, and renal failure.²¹⁴ In addition, there is clinical evidence to indicate that pre- or postoperative low-molecular-weight dextran treatment may not be effective in augmenting free flap viability.^{215–217}

Thrombolytic agents

While early detection and re-exploration are crucial for salvaging failing free flaps, those flaps unresponsive to standard interventions may benefit from the selective use of thrombolytics for lysing formed thrombi.²¹⁸ The common thrombolytic agents that have been used successfully in clinical free flaps are streptokinase,^{219–227} and recombinant tissue plasminogen activator (tPA).^{228–231} The effective doses of these thrombolytic agents have also been discussed.^{199,200} Results from these studies are encouraging and these agents are now commonly used, particularly in take-back situations. However, most, if not all, of these studies were small or in the form of case reports.

Antispasmodic agents

Papaverine, nifedipine, and lidocaine are the most common topical antispasmodic drugs used in clinical microsurgery. Papaverine is an opiate alkaloid, which relaxes vascular smooth muscle, especially during spasms. It inhibits phosphodiesterase, the enzyme involving the breakdown of cyclic adenosine monophosphate (cAMP), resulting in accumulation of cAMP, causing vasodilation.²³² Nifedipine is a calcium channel blocker. The mechanism of action is inhibition of calcium influx into the arterial smooth-muscle cells, thus causing smooth-muscle cell relaxation.²³³ The vasodilator effect of lidocaine is the result of its effect on the Na⁺/Ca²⁺ ion exchanger pump causing a reduction in intracellular calcium content, resulting in vasodilation.²³⁴

Preischemic and postischemic pharmacological conditioning against ischemia–reperfusion injury in free flap surgery

In the past 20 years, research in ischemia–reperfusion injury in cardiac and skeletal muscle has been focused on the efficacy and mechanism of preischemic and postischemic conditioning against ischemia–reperfusion injury.²³⁵ This information is important because it may provide insight into the identification of new drugs for the prevention or salvage of skin and skeletal muscle from ischemia–reperfusion injury in free flap and replantation surgery.

Local preischemic conditioning against ischemia–reperfusion injury in skeletal muscle

The phenomenon of preischemic conditioning against ischemia–reperfusion injury was first recognized in dog myocardium.²³⁶ Subsequently, Mounsey *et al.* in our laboratory demonstrated this phenomenon for the first time in pig muscle flaps.^{237,238} Specifically, we reported that instigation of three cycles of 10 minutes occlusion/reperfusion in pig latissimus dorsi muscle flaps with a vascular clamp reduced the muscle infarction by 40–50% when these muscle flaps were subsequently subjected to 4 hours of warm ischemia and 48 hours of reperfusion. This observation was confirmed with pig gracilis muscle flaps in our laboratory.^{239,240} Subsequently, other investigators reported that local preischemic conditioning also augmented ischemia–reperfusion injury tolerance in rat skeletal muscle,^{241–243} and in the skin of cutaneous and musculocutaneous flaps in the rat.^{244,245} Local preischemic preconditioning also attenuated vascular dysfunction in rat skeletal muscle²⁴⁶ and capillary no-reflow in rat and dog skeletal muscle induced by sustained ischemia and reperfusion.^{247,248} However, local preischemic conditioning has clinical limitations because it requires instigation of brief cycles of ischemia and reperfusion by repeated clamping of the vascular pedicle and there is the risk of damaging the blood vessels. However, understanding the mechanism of local preischemic conditioning may provide insight into the identification of pharmacological treatment to mimic local preischemic conditioning. Using pharmacological probes, we uncovered that the mechanism of local preischemic conditioning in pig latissimus dorsi muscle flaps involved adenosine A₁ receptor–protein kinase C–mitochondrial K_{ATP} channel-linked events.^{249–254} Martou *et al.* in our laboratory demonstrated the efficacy of preischemic conditioning against ischemia–reperfusion injury in *ex vivo* human rectus abdominis muscle strips.⁶² This model is now being used to study the pharmacological preischemic conditioning against ischemia–reperfusion injury in *ex vivo* human skeletal muscle strips.

Remote preischemic conditioning against ischemia–reperfusion injury in skeletal muscle

Of interest was the report from Oxman *et al.* that the instigation of a 10-minute cycle of occlusion and reperfusion in a hind limb by tourniquet application preconditioned the heart against reperfusion tachyarrhythmia in the rat.²⁵⁵ This is known as remote preischemic conditioning. Based on this technique, Addison *et al.* in our laboratory demonstrated for the first time the efficacy of noninvasive hind limb remote preischemic conditioning for the global protection of skeletal muscle against ischemia–reperfusion injury.²⁵⁶ Specifically, we demonstrated that the instigation of three cycles of 10 minutes of occlusion/reperfusion in a hind limb of the pig by tourniquet application (~300 mmHg) under general anesthesia protected multiple skeletal muscles at various distant locations from infarction when these muscles were subsequently subjected to 4 hours of ischemia and 48 hours of reperfusion (Fig. 23.6). We also observed that mitochondrial K_{ATP} channels play a central role in the trigger and mediator mechanisms of hind limb remote preischemic conditioning of pig skeletal muscle against infarction.²⁵⁷

Fig. 23.6 Noninvasive remote preischemic conditioning for global protection of skeletal muscle against ischemia–reperfusion injury. Instigation of three cycles of 10 minutes occlusion/reperfusion in a hind limb of the pig by tourniquet application (~300 mmHg) protected latissimus dorsi, gracilis, and rectus abdominis muscle flaps from infarction when subsequently subjected to 4 hours of ischemia and 48 hours of reperfusion.

Subsequently, Moses, another of our research fellows, demonstrated that the infarct-protective effect of remote preischemic conditioning in pig skeletal muscle was biphasic²⁵⁸ and the time course was similar to that seen in local preischemic conditioning in the myocardium of rabbits^{259–261} and dogs²⁶² and in the skeletal muscle of rats.^{263,264} Specifically, an early phase of infarct protection started immediately after hind limb remote preischemic conditioning, waned within 4 hours, and completely disappeared in less than 6 hours after remote preischemic conditioning (Fig. 23.7). The late phase (second window) of infarct protection (re) appeared within 24 hours after hind limb remote preischemic conditioning and lasted up to 72 hours. More importantly, it was observed that sarcolemmal and mitochondrial K_{ATP} channels play a central role in the trigger and mediator mechanism, respectively.²⁵⁸ The logical approach in the future is to identify a nonhypotensive prophylactic drug (e.g., sarcolemmal K_{ATP} channel opener) to be taken orally 24

Fig. 23.7 Biphasic time course of the infarct-protective effect of remote ischemic preconditioning. Muscle flaps in control and treatment groups were subjected to 4 hours of ischemia and 48 hours of reperfusion. In the treatment groups, 4 hours of ischemia began at 0, 4, 6, 8, 24, 28, 36, 48, 72, or 96 hours after remote ischemic conditioning. Infarct protection occurred at 0–4 hours and 24–72 hours after remote ischemic conditioning. Values are mean ± SEM; n = 8 flaps. Means with an asterisk are similar and are significantly different from the means without an asterisk (n = 8 flaps, P < 0.05).

hours before surgery to achieve 48 hours of uninterrupted perioperative protection of skeletal muscle from ischemia–reperfusion injury in elective microsurgery. Recently, we observed in pigs that the clinical drug nicorandil induced 48h uninterrupted muscle infarct protection 24h after intravenous injection.²⁶⁵

Postischemic conditioning for augmentation of free flap viability

Khiabani and Kerrigan reported that local intra-arterial infusion of the NO donor SIN-1 to pig latissimus dorsi myocutaneous flaps and buttock cutaneous flaps by means of a catheter for 18 hours after 6 hours of ischemia was effective in salvaging the ischemic skin and muscle from reperfusion injury.²⁶⁶ However, this technique is too invasive for routine clinical use. McAllister *et al.* in our laboratory reported that instigation of four cycles of 30-second reperfusion/reocclusion at the onset of reperfusion after 4 hours of ischemia reduced pig latissimus dorsi muscle flap infarction by ~50%, assessed at 48 hours of reperfusion.²⁶⁷ This phenomenon is known as postischemic conditioning and was first demonstrated in dog myocardium.²⁶⁸ Subsequently, Park *et al.* demonstrated that postischemic conditioning also protected contractile function of rat extensor digitorum longus muscle subjected to 3 hours of ischemia and 5 days of reperfusion.²⁶⁹ McAllister also demonstrated that the mechanism of postischemic conditioning in pig skeletal muscle involved lowering of mitochondrial free Ca^{2+} content, closing of mitochondrial permeability transitional pores (mPTP), and increase in muscle ATP content. The infarct-protective effect of postischemic conditioning was mimicked by intravenous injection of the mPTP opening inhibitor cyclosporine A (10 mg/kg) at 5 minutes before reperfusion.²⁶⁷ This observation suggests that cyclosporine A may be a potential clinical therapeutic agent for salvaging ischemic replants and muscle free flaps from reperfusion injury. Mowlavi *et al.* reported that preischemic or postischemic cyclosporine A treatment (15 mg/kg, orally) increased rat gracilis muscle viability when subjected to 4 hours of ischemia and 24 hours of reperfusion.²⁷⁰ However, statistical significance was achieved in preischemic treatment but not postischemic treatment. A higher oral dose of cyclosporine A may be required for postischemic treatment because, according to McAllister *et al.*, the effective dose of cyclosporine A for postischemic conditioning in pig skeletal muscle flap was 10 mg/kg intravenously.²⁶⁷ At the present time, an *in vitro* model is being used in our laboratory to study the efficacy and mechanism of cyclosporine A in salvage of *ex vivo* ischemic human rectus abdominis muscle from reperfusion injury.^{271,272}

Recently, McAllister *et al.* also reported that preischemic or postischemic treatment with the Na^+/H^+ exchanger inhibitor cariporide (3 mg/kg, intravenously) induced a significant decrease in mitochondrial free Ca^{2+} content and infarct size in pig latissimus dorsi muscle flaps when subsequently subjected to 4 hours of ischemia and 48 hours of reperfusion.²⁷³ This observation further supports our finding that the mechanism of postischemic conditioning involves lowering of mitochondrial free Ca^{2+} content and inhibition of opening of the mPTP, and the mPTP opening inhibitor cyclosporine A is effective in salvage of ischemic pig skeletal muscle from reperfusion injury.

Conclusion and future directions

Flap pathophysiology

Surgical and vascular delay are the only proven clinical techniques for augmentation of pedicle skin flap viability. However, these surgical manipulations are time-consuming and costly. Similarly, preischemic and postischemic conditioning are effective in protecting skeletal muscle flaps from ischemia–reperfusion injury in laboratory animals, but surgeons are reticent to conduct a clinical trial on the efficacy of ischemic preconditioning and postconditioning against ischemia–reperfusion injury in free flap surgery because these techniques are invasive and/or time consuming. Therefore, there is the need to continue to search for pharmacological therapy to increase skin blood flows and distal perfusion in pedicle skin flaps and to protect the skin and muscle from ischemia–reperfusion injury in free flaps and replant surgery.

Flap pharmacology

The angiogenic cytokine VEGF₁₆₅ is known to cause local vasodilation and increases in capillary density (angiogenesis), resulting in augmentation of skin blood flow and viability in random pattern skin flaps in the rat. However, review of the literature thus far indicates that the skin flap viability in VEGF₁₆₅ gene or protein therapy was about 15–20% lower than that of surgical delay.^{187,197} In addition, angiopoietin-2 is known to induce arteriogenesis in mouse ischemic hind limb.²⁷⁴ Therefore, future studies are recommended to investigate if combined local VEGF₁₆₅ and angiopoietin-2 protein or gene therapy will synergistically increase capillary and arteriole density, resulting in maximizing skin viability in random skin flaps.

In the cases of ischemic–reperfusion injury in skeletal muscle, future studies are required to understand the mechanism of preischemic and postischemic conditioning in protecting skeletal muscle against ischemic–reperfusion injury in laboratory animals *in vivo* and human skeletal muscle *in vitro*. This probably will include studying the role of Na^+/H^+ exchangers, mitochondrial free Ca^{2+} content, and opening of the mPTP in the pathogenesis of ischemia–reperfusion injury. This area of research will most likely lead to the identification of pharmacological agents to protect skeletal muscle from ischemia–reperfusion injury when given before or after ischemia. Further studies are also recommended to investigate the additive effect of combined preischemic and postischemic pharmacological conditioning to protect skeletal muscle from ischemia–reperfusion injury. Last but not least, our published human skeletal muscle strip culture technique⁶² is recommended for screening drugs for clinical studies of preischemic and/or postischemic pharmacological conditioning of skeletal muscle against ischemia–reperfusion injury.^{62,272,275}

Principles and techniques of microvascular surgery

Fu-Chan Wei, Nidal F. Al Deek, and Sherilyn Keng Lin Tay

 Access video lecture content for this chapter online at expertconsult.com

SYNOPSIS

- Microvascular surgery refers to the surgical coaptation of small vessels usually around 1 mm in diameter under microscope magnification. Microsurgery is a broader term not only limited to blood vessels but also refers to coaptation of tiny nerves and lymphatics.
- This technique has evolved significantly over the last four decades, starting from revascularization and replantation in 1960 to free-flap surgery.
- The development of the operating microscope, microinstruments, and ultra fine sutures have greatly aided its widespread use.
- Despite various techniques having been developed for the handling of small vessels, the most commonly used techniques are still the end-to-end and end-to-side anastomosis and coupling devices. Difficult situations such as vessel diameter discrepancy, inadequate vessel length, and poor vessel quality can usually be overcome with special techniques.
- Advances in microsurgery leading to consistently high success rates have made free tissue transfer a cost-effective, first-line option in modern reconstructive surgery with superior results and high patient satisfaction compared with conventional methods. Microsurgery, however, is mentally and physically demanding. The need for special training cannot be overemphasized.
- Thorough preoperative planning, flexibility of the surgical plan, and flawless execution are mandatory for successful free flap surgery.
- Clinical assessment remains the gold standard in free flap monitoring. Early detection of a failing free flap with prompt intervention greatly improves the salvage rates. Pharmacological agents such as low-dose heparin, PGE1 and dextran are also useful. Complications of free tissue transfer are not only due to vascular compromise; inadequate planning, inappropriate flap selection and/or flawed execution can compromise the flap and/or the functional and aesthetic outcomes.
- Refined microsurgical techniques and improved postoperative care such as specialized microsurgical intensive care units have led to a 96–98% success rate in developed centers nowadays. If the first microsurgical reconstruction fails, a second microsurgical reconstruction can still be attempted with good results after identifying and managing potential causes.

- Microsurgery will not decline but will continue to evolve. Microsurgery has indeed revolutionized our approach to reconstructive challenges, and with further refinements, we will see an even wider application; particularly, in the fields of supermicrosurgery, free-style free flaps, and composite tissue allotransplantation.

Introduction

Microsurgery is a general term for surgery requiring the operating microscope. Depending on the structure operated on and its size, terms such as microvascular surgery (surgery on blood vessels around 1 mm), microneural surgery, micro-lymphatic surgery, and microtubular surgery, etc., can be coined.

Supramicrosurgery is an extreme microsurgery and refers to anastomoses of vessels around 0.5 mm in diameter (0.3–0.8 mm), invaluable in lymphatic reconstruction and perforator-to-perforator anastomosis.^{1,2}

Reconstructive microsurgery utilizes microsurgical and supramicrosurgical techniques in procedures such as revascularization, replantation, and auto- or allotransplantation to solve problems arising from traumatic injuries, congenital deformities, and tumor ablation. However, some of these procedures are performed under loupe magnification ($\times 2.5$ – 8), including vessel coaptation, especially when the diameter is not too small (usually around 3 mm).

It is worth noting that microsurgical techniques and, to a lesser degree, supramicrosurgery are not limited to plastic surgery; however, the scope of practice within plastic surgery remains the most diverse in modern surgery.

The era of microsurgery began with the invention of the microscope in 1920. But the improvement in magnification and illumination and the development of microinstruments and ultrafine sutures are the leading factors for the widespread use of the techniques.

Our approach to micro- and supramicrosurgery has changed over time. Consistently reported high success

rates of 97–100%, cost-effectiveness, superior functional, aesthetic, and psychological outcomes compared with other techniques have changed the indication for microsurgery from being the last resort after failure of other options into the first choice and reversed, as a result, the reconstructive ladder.

However, and not being confused as a “double-edged sword”, microsurgery comes with a high price, demanding experience and resources. But with professional training, specialized infrastructures, dedication, and support, microsurgery can be performed daily with convenience.

The focus of this chapter is the principles and techniques of basic and advanced microsurgery and free tissue transfer, including perforator free flaps, free-style free flaps, allotransplantation, and possible future directions. Revascularization and replantation are specifically covered in other chapters.

Tools

Since the introduction of the triangulation technique for vessel repair by Alexis Carrel, the diameter of vessels that can be anastomosed has become progressively smaller, due largely to developments in surgical techniques, surgical instrumentation and microsutures, and improved optics in present-day microscopes.

Magnification under adequate illumination allows more accurate perception of operative anatomy and positioning of instrumentation, with improved outcomes and facilitation of procedures that would be impossible to undertake without assisted vision. Intraoperative magnification also reduces surgeons' fatigue as a result of improved ergonomics. Two types of optical system are used by surgeons to produce magnification – the surgical microscope and loupes.

Surgical microscopes

The basic sophistication of today's operating microscope includes binocular head with adjustable eyepieces and a teaching head to allow two people to work with magnification in the operating field; there could be a third head for digital recording. The heads should independently pivot and have separate magnification levels with the flexibility to be retrofitted with a camera to document the procedure on an SD card or DVD as well as to allow colleagues to view the operation in real time.

Tilt, focus, and zoom can be controlled via a foot pedal or a hand control panel; the first keeps the surgeon's hands free to perform the surgery without interruption, but necessitates coordination; the second option could be more practical as it keeps all functions in one accessible place.

Antimicrobial-coated surfaces and internally routed cables are very important because the controls, lighting, and documentation technology nowadays require wiring; loose wiring can get in the way of the surgical team and can harbor bacteria.

40× magnifications can be provided by some microscopes with instant magnification change, a variable working distance, and precise XY positioning.

Some microscopes such as Leica and OPMI Pentero incorporate intraoperative fluorescence tools to assist the surgeon, which is an invaluable technique to check perfusion before and after, in lymphatic microsurgical reconstruction, and precise tumor ablation in neurosurgery.

The modern operating microscope can be mounted on a stand, placed on a table top, or worn on the surgeon's head. Some of them can be hung on the ceiling or wall to conserve floor space in the surgical suite. Microscopes that can be moved from one room into another and used by different surgical specialties are very desired and cost-effective; however, ophthalmic surgical microscopes could be an exception due to the specialized lighting, focusing, and magnification requirements.

When using the microscope, choosing the appropriate level of magnification is important in order to maneuver the instruments and perform the anastomosis efficiently. Low magnification (6×–12×) can be used for vessel preparation and suture tying while middle magnification (19×–15×) can be used for suture placement. High magnification is usually only required for very small vessel anastomosis and inspection of the anastomosis. For tips for use, see [Box 24.1](#).

Loupes

Loupes can provide magnifications of 2.5×–8× and may be mounted on glasses or headbands. They are cost-effective, portable, and offer operator freedom.³⁰ Enhanced visualization provided by loupes is invaluable for precise dissection of tissues and placement of instruments and sutures. In experienced hands, high-magnification loupes can even provide an effective alternative to the operating microscope for vessels as small as 1 mm. A retrospective study of 200 consecutive free microvascular tissue transplantations compared the performance of free tissue transplants with 3.5× loupes and the operating microscope.²⁴ There was no difference in outcome between the two groups, with free-flap success rates of 99% for both the loupe and the microscope groups. However, microscopes were required when performing anastomoses in children and on vessels of 1.5 mm or less in diameter. Despite these studies, most centers still use the microscope for its greater range of magnification and light sources. This is particularly important for smaller-vessel anastomoses in the era of perforator flap, free-style, and supramicrosurgery practice.

BOX 24.1 Tips for using surgical microscopes

- Familiarize yourself with the microscope
- Spend time getting the position right, making sure that the interpupillary distance and diopter correction are right
- Use an adjustable seat if you intend to sit
- Sit comfortably with feet flat on the ground to provide a stable base
- Upper extremities should be well supported, resting on folded drapes as necessary, to minimize fatigue and tremor
- Focus should be adjusted with the scope at highest magnification before starting

Historical perspective

The concept of vascular repair was first proposed by Paré in 1552. However, it was two centuries later before the first successful brachial artery repair was performed in 1759³ and even later in 1897 when Murphy reported his successful end-to-end anastomosis of the femoral artery by invagination of vessels with fine silk.⁴ Building on Murphy's work, Alexis Carrel reported a technical breakthrough for performing end-to-end vascular anastomoses using the triangulation method in 1902.⁵ This work was further expanded in collaboration with Guthrie, and for his contributions in "vascular suture and the transplantation of blood vessels and organs", Alexis Carrel was awarded the Nobel Prize in 1912.

Experimental limb replantation in dogs and other models continued in microvascular surgery. However, it was the isolation of heparin from the liver by a medical student, McLean,⁶ and its clinical introduction as an anticoagulant to control clotting two decades later⁷ as well as the use of the operating microscope that gave microvascular surgery a giant leap forward.

The compound microscope was invented by Janssen in 1590 and subsequently mass-produced by Carl Zeiss for laboratory research in the late 1800s. However, it was not until 1921 that Carl-Olof Siggesson Nylen, a Swedish otologist, first used a modified monocular Brinell-Leitz microscope for animal surgery and then, later in November of the same year, in a patient with chronic otitis and pseudofistula symptoms.⁸ Nylen's microscope was soon replaced by a binocular microscope, developed in 1922 by his colleague Gunnar Holmgren. In 1946, Perritt applied the use of the microscope to ophthalmology.

The stage for modern microvascular surgery was set in 1960 when vascular surgeons Jacobson and Suarez^{9,10} introduced the diploscope, a stereoscopic microscope for simultaneous use by two surgeons, for anastomoses of vessels as small as 1 mm in diameter. From this point onwards, the microscope found extensive use in the fields of peripheral nerve surgery,^{11,12} plastic and reconstructive surgery,¹³ experimental transplantation,¹⁴ and neurosurgery.

The first clinical application of microvascular surgery was in replantation. Malt and McKhann first reported the successful replantation of several arms in 1964¹⁵ whilst the first complete thumb replantation was performed in 1965 by Konatsu and Tamai with the aid of a microscope.³ Young

reported on their series of second toe-to-hand transfers in 1966¹⁶ and a year later, Cobbett performed the first successful great toe-to-thumb transfer in a human being.¹⁷

The first experimental flaps based on the superficial epigastric vessels were transplanted in dogs and reported by Krizek *et al.* in 1965.¹⁸ Antia performed the first clinical free flap, but this was only reported several years later, in 1971.¹⁹ This dermolipomatous groin flap for facial defect reconstruction was, however, complicated by infection and at least partial necrosis occurred. In 1970, the omental free flap by McLean and Buncke was the first fully successful free flap²⁰ and in 1973, Daniel and Taylor reported transfer of the first groin flap.²¹

New flaps, mainly musculocutaneous, were designed next and the indications for their use were expanded over the next few decades. Complication and failure rates declined^{22,23} and success rates today range between 95.9 and 99%,^{24,25} compared to 74–91%²² in earlier times.

During the late 1980s and into the 1990s, research focused on anatomy, flap physiology, better donor sites, and improved survival. But it was not until the late 1980s that cutaneous flaps based on perforator vessels finally evolved from conventional musculocutaneous flaps, and intramuscular dissection was born with preservation of function and major vessels. The first true perforator flap was the deep inferior epigastric artery perforator flap first reported in 1989 by Koshima and Soeda.²⁶ The next milestone in free flap surgery was the free-style flap that allowed the harvest of a paddle of skin based on an audible perforator detected by a hand-held Doppler in an area that had not been previously adequately studied, alleviating concerns regarding vascular anomaly and leaving the door open for up to 400 perforator flaps.

Reconstructive microsurgery witnessed another great achievement when allotransplantation became a reality after the first successful hand transplantation in 1998 in Lyon, France, and in January of 1999 in Louisville, USA.^{27,28} The international experience has reached 107 transplanted hand/upper extremities in 72 patients by the year 2014.²⁸

The first partial face transplantation was performed in 2005 in Lyon, France, too. However, the first total face transplantation was performed in 2010 in Barcelona, Spain. So far, 29 partial, near-total, and total face transplantations have been performed.²⁹

It is worth saying, though, that the widespread application of allotransplantation will not depend on advances in microsurgery as much as immunosuppression!

Types

Two types of loupe are used in surgery: the compound (Galilean) and prismatic loupe. In contrast to single-lens off-the-shelf magnifying reading glasses, compound loupes have significantly superior optics. These consist of two magnifying lenses separated by air, achieving higher magnification, greater depth of field, and better working distance. However, image quality tends to become distorted at magnifications above 2.5 $\times$ and all such lenses create a “halo” effect at the periphery of the visual field which may disturb the surgeon. These drawbacks are counterbalanced by their relatively low cost and light weight and they are widely used and available from most manufacturers.³¹

Prismatic loupes provide higher optical quality because of a Schmidt prism, which lengthens the path of light through a series of mirror reflections inside the loupe. They can provide improved magnification, wider fields of view, and longer depths of field or working distance, but are 30–40% heavier, more expensive than compound loupes, and more easily damaged.³¹

Choosing loupes

While choice of magnification is largely dependent on the surgeon's preference, as a rough guide, a 2.5 $\times$ magnification is often sufficient for hand surgery and flap harvesting. If the loupes are to be used for perforator dissection or anastomoses, 3.5–4.5 $\times$ magnifications may be more suitable although 2.5 $\times$ is sufficient enough for perforator dissection. It is important to note that both the field of view and depth of field decrease with increasing magnification, while the weight of the loupes increases. Loupes with a magnification higher than 4.5 $\times$ tend to be cumbersome and too heavy for daily use (especially if they are prismatic), resulting in neck tension and increased fatigue. In such instances, opting for the microscope might be a better option.

Once the magnification has been chosen, other features such as lens design, working angle, and distances need to be considered. Some might choose to have the loupes mounted on glasses or headbands, while others might prefer through-the-lens (loupes mounted to the lenses of the frames) over the flip-up or snap-fit type. The latter permits cheaper changing of the magnification and the ability to change the lens prescription more conveniently. Some manufacturers can also supply headlights for use where additional lighting may be required – particularly useful with the use of higher magnifications.

Microsurgical instruments

Even with excellent optical systems, it would not have been possible for microsurgical techniques to have evolved without parallel refinements in microsurgical instruments and suture materials. Many fine instruments have been available for many years from jewelers but most have been developed during research on vascular, lymphatic, and neural microsurgery. A confusing array of instruments and supplies for microsurgery is now available, but with experience, most microsurgery can be done with surprisingly few instruments and most surgeons will become proficient with a reasonably small set.

Essential features in all microsurgical instruments include fine tips to spread, hold, or cut delicate tissue and suture, a nonreflective surface and comfortable handles that close easily to prevent fatigue.³² Many of the instruments used in microvascular surgery will also be spring-loaded, and choosing the right spring tension is important – too weak and the tips will close all the way just by holding the instrument; too firm and your hand will fatigue after a short period of use.

Most microinstruments are made of heat-hardened stainless steel, which is more resistant to wear and tear. They are prone to magnetization and should be stored on demagnetized or nonmagnetic shelves. If an instrument becomes magnetized, placing it in a coil demagnetizer attached to a regular alternating current supply and withdrawing it slowly will help. Antimagnetic materials such as titanium are becoming popular, promising to be rust-free and lighter in weight. In reality, however, they too can become magnetized. Most microinstruments are available with a round or flat handle, and range from 10–18 cm in length depending on surgeon preference and depth of working field. In general, shorter instruments are used when the anastomosis is closer to the surface, for example, in hand surgery, while instruments longer than 18 cm are used for procedures involving free tissue transfer. Longer instruments may also be balanced such that the balance point rests in the webspace. The slight counterweight at the end of the instrument reduces fatigue and allows better control and precision.

All instrument manufacturers give instructions for maintenance, and it is extremely important to follow these instructions to ensure maximal performance of the microinstruments. It is advisable to store the microinstruments in specially designed instrument cases and to protect their fine tips with silicone or rubber tubes. To be effective, they need to be fine-tipped with the jaws meeting precisely. The user should therefore minimize damaging them by not using them for anything other than handling vessels and nerves. Blood and contaminants should be regularly cleaned off by the scrub nurse during the course of surgery and finally rinsed with distilled or deionized water to avoid staining of the instruments. High chloride concentrations should be avoided as they lead to pitting and corrosion.

Types

Scissors

Microvascular scissors should be spring-loaded with sharp but gently curved blades and slightly rounded tips. When held closed, they can be used safely as a dissecting probe without the danger of damaging the vessel. Those designed for trimming the adventitia off the vessel end have straight blades with sharp tips and are also good for stitch-cutting.

Needle holders

Spring-loaded microvascular needle holders are held like pencils, resting on the first web. The handle is ideally rounded to allow the instrument to be rolled between the index and middle fingers and the thumb during the passing of the needle. Flat handles are also available. The jaws should be thin and gently curved with narrow shoulders to be able to grasp the microsutures. Needle holders could be also straight but the curved are usually finer at the tip and more suitable for vessel dilation. Some needle holders come with a ratchet

lock to facilitate the parking and passing of the needle; however, in inexperienced hands, the locking and unlocking maneuvers easily damage the needle and can cause significant trauma to the tissues handled; an unlocking needle holder is preferred.

Forceps

The jeweler's forceps were originally designed by the Swiss Dumont factory and is characterized by a flat handle and sharply narrowing tips. These tips must be aligned with a precision of 1/1000 inch, the diameter of the 10-0 nylon. When closed with moderate pressure, the jaws should meet evenly over a length of 3 mm so that the suture can be easily handled. They are further classified by the width of the contact surface, the narrowness, and the overall configuration. No. 2 forceps has wide jaws and can be used as needle holders. No. 3 forceps is straight and fine-pointed and no. 5 forceps has very fine tips. These are suitable for tissue handling and thus are commonly used in microsurgery. They are used almost continually in the nondominant hand for tissue handling, receiving the needle, and suture tying. No. 7 forceps has curved jaws. Microforceps are also available with round handles, although the flat handle is the preferred style. The most commonly used forceps are smooth-tipped, but the forceps can also be toothed, curved, angled, or equipped with a hole in the tip for better grasping. The angled forceps allows a grip that is parallel or perpendicular to the working surface and is useful for reaching under vessels, tying knots, and performing patency tests. A modified jeweler's forceps with a slender, smoothly polished nontapering tip can be used to dilate vessels gently.

Vascular clamps

The vascular clamps that are commonly used today have evolved significantly since the bulldog clamps that Jacobson used in his historical first microanastomoses, and many of the earlier models are now obsolete. The clamps developed by Henderson *et al.*³³ in 1970 required a small key and screw mechanism for adjustments and were not suitable for vessels less than 1.5 mm. In 1974, Acland³⁴ developed a double microvascular clamp with a small wire frame and a stay suture-holding device. Although it is still available today, it has largely been superseded by modifications of the design by Tamai³⁵ with the two clamps incorporated into a sliding bar.

Clamps are ideally atraumatic and have sufficient closing pressure to prevent bleeding and slippage but not damage the vessel wall. They are available as single clamps or double approximator clamps. In general, clamps are divided into those used on veins or arteries. Those designed for veins have a smaller closing pressure and usually a flat jaw all the way to the end. Those designed for arteries have greater closing pressure with a slight incurve at their tip to prevent crushing of the vessel wall. Generally, clamps marked with a V may be used for veins and most arteries, although particularly thick-walled veins may require the use of clamps marked with A.

To optimize closing pressure, clamps are available in a variety of sizes for different vessel diameters (i.e., the external diameter of the vessel in the natural state of full dilation). Pressure is inversely proportional to the vessel size – the

smaller the vessel inside the clamp, the higher the pressure exerted on the vessel by the clamp. Ideally, a clamp exerts a pressure of 5–10 g/mm² and 15–20 g/mm² when used on the largest and smallest vessels in its size range, respectively. Where possible, use the smallest appropriate clamp to minimize crushing the vessel with too large a clamp. Although they can be applied by hand or artery forceps, special clamp applicators for the smaller clamps are available to ensure the accurate placement and removal of the clamps without damage to the vessels and to the calibration.

In spite of the refinements, clamps, arguably, can cause intimal lesions, occupy space in confined sites and have a risk of backwalling due to vessel flattening. Plaque-filled atherosclerotic vessels could be a challenge. For all of these reasons, clampless anastomosis may be appealing to some surgeons. Preliminary clinical experience with a CE-certified thermosensitive gel clinically proven in cardiovascular surgery has been reported with high success rates.³⁶ The gel provides circular stenting and gentle distension of the vessels for a safe and blood-free anastomotic site, and it dissolves completely with cold saline irrigation after the anastomosis is done. This technique may find its way in atherosclerotic arteries and confined anastomosis sites, but more studies are warranted.

Bipolar coagulator

The development of the bipolar coagulator in 1956 promoted further development of microsurgery because a completely bloodless field was now attainable. The bipolar coagulator conducts current between the tips of the jeweler's forceps, producing heat damage only within a very small area between the instrument tips, allowing precise coagulation of small branches as close as 2 mm to the main vessel in place of vascular clamps.^{37,38} Its power setting must be optimized as too much power results in spreading of the heat with inadvertent damage to the surrounding tissues. Some surgeons prefer to use this for dissection instead of a knife or scissors, and bipolar scissors are now commercially available.

Irrigation and suction

Having a clear view of the vessel walls is imperative for successful anastomosis and even a small amount of blood may obscure the field. Constant irrigation with Ringer's lactate or heparinized saline and the use of suction are useful.^{39–41} Irrigation serves several purposes: to prevent desiccation of vessels, sticking of suture to tissue, to wash away blood and clots to provide a good view, and to wash away any prothrombotic factors that might act as a nidus for thrombus formation and to improve patency.^{42–44} This may be performed through a continuous irrigation system⁴⁵ with a smooth and blunt irrigation tip or more simply with a 5–10-mL syringe and a lacrimal cannula or 24-gauge angiocath.

There have been many suggested ways of suction, varying from suction through small segments of moistened hydrocellulose sponge or gauze, to suction tubes that drain through a perforated background plate and to homemade suction tips with an intravascular catheter attached to a 10-mL syringe placed over the normal suction tubing.⁴⁶ On occasion, when there is only a small amount of ooze, cellulose spearheads (eye sponges) on a polypropylene handle afford precise control and immediate absorption.

Microsutures

Buncke⁴⁷ described making his first microneedle by drilling a hole in a 75-mm stainless steel wire. This needle held a single strand of silk and was used to replant a rabbit's ear by anastomosis of 1-mm vessels. Soon a commercially available needle was developed by Acland,⁴⁸ working with the Springler-Tritt company.

Since then, microsurgical sutures have been available in combinations of different materials, suture sizes (8-0 to 12-0), tensile strengths, and needle configurations. The microsuture is considered to be the standard means of vascular anastomosis. The most widely used sutures are 9-0 monofilament nylon on a 100- μ m curved needle and 10-0 nylon on a 75- μ m needle. The choice is usually made based on the vessel wall thickness and diameter, with 9-0 sutures used for vessels of 2 mm or more in diameter and 10-0 for those between 1 and 2 mm in diameter. Smaller suture-needle combinations are available but reserved for use by experienced microsurgeons with very fine instruments, for very distal fingertip replantations, anastomoses in small children, and in lymph vessel anastomosis. Microneedles are typically shaped as three-eighths of a circle but are also available as a half-circle or straight (rarely used now), with round, tapered, or spatula-shaped tips to prevent damage to the fragile vessel wall. The commonest suture used in microsurgery is nonresorbable nylon which has low tissue reactivity and knot-holding ability, although polypropylene is preferred by some as it slides and handles better within the tissue.

Special considerations for supermicrosurgery

Supermicrosurgery was coined by Isao Koshima to describe anastomosis of blood vessels smaller than 1 mm (0.3 to 0.8 mm).¹ The technique has its application, mainly in very distal replantation, lymphatico-venous anastomosis, and perforator flaps.^{1,2} Special instruments are crucial for success. These instruments include a surgical microscope with the highest currently available magnifying power, with 50 $\times$ magnification, the thinnest titanium forceps, and the smallest surgical needle (12-0 nylon).

The microscope has high-power (50 $\times$) magnification and allows a 20-cm working distance, which was impossible with microscopes of 20 $\times$ magnification.²

Anastomotic devices

Despite the fact that microsutures are nowadays relatively inexpensive, reliable, and readily available, they do not fully meet the criteria of an "ideal" anastomosis. Many nonsuture techniques have developed in the search for faster and less traumatic anastomosis.

In 1962, Nakayama *et al.*⁴⁹ introduced an anastomotic device consisting of two metallic rings and interlocking pins that remain *in situ* as a permanent implant. The Unilink system developed by Östrup and Berggren in 1986,⁵⁰ the 3M and ACE coupling devices that were adaptations of this ring-pin device, is currently marketed under the name Microvascular Anastomotic System. This system consists of two disposable rings made of high-density polyethylene with a series of six to eight evenly spaced 0.16-mm diameter stainless steel pins that are implanted with a reusable anastomotic instrument.

The ring-pin device is a simple, efficacious, and faster technique of anastomosis and has the added advantage of not disturbing the intima in the anastomosis. It is the most successful and commonly used coaptation device. It has yielded excellent patency rates of up to 100%, even in fields that have been previously irradiated.⁵¹⁻⁵³ The rings come in a variety of sizes from 1 to 4 mm in diameter, allowing the coaptation of vessels ranging from 0.8–4.5 mm with a maximal wall thickness of 0.5 mm, and the device is suitable for both end-to-end and end-to-side anastomosis. It is contraindicated in peripheral vascular disease, areas with ongoing radiation therapy, active infection, concurrent diabetes, and corticosteroid therapy.

In an experimental comparison of venous anastomosis with use of this device, the sleeve technique, and the standard end-to-end technique, patency rates were 100%, 80%, and 95%, respectively. In an analysis of 1000 consecutive venous anastomoses with this method in breast reconstruction, Jandali *et al.*⁵⁴ reported an anastomotic time of 2–6 minutes with a 99.4% patency rate. No total flap losses were encountered. It has also been used effectively in end-to-side anastomosis of veins in head and neck free-flap reconstruction, with 99–100% patency.^{53,55} To resolve the problems of a permanent rigid ring, an absorbable anastomotic coupler was developed and has been used experimentally and clinically, achieving patency rates of 92.9–100%⁵⁶⁻⁵⁸ and 95%, respectively.⁵⁹ The ring was completely absorbed at 70 days to 30 weeks after anastomosis. Although used mainly for venous anastomoses, the mechanical coupling device has been also used successfully in performing arterial anastomoses, with up to 100% patency rate,⁶⁰⁻⁶³ proving to be expeditious, safe, and reliable. Contraindications of using this device on arterial anastomosis include thick-walled vessels that do not adequately evert, diameter discrepancies of more than 1.5:1 ratio, nonpliable vessels stiffened by prior radiotherapy or calcification, and any artery less than 1.5 mm in diameter.⁶⁰

The nonpenetrating microvascular stapler, available as a disposable device (VCS clip applier system), reported by Kirsch *et al.*,⁶⁴ uses nonpenetrating titanium clips applied in an interrupted, everting fashion. The clips come in four sizes, ranging from 0.9 to 3.0 mm, and demonstrate a reduced anastomotic time and higher patency rate. In an end-to-end anastomosis, two stay sutures are first placed at 180° to facilitate the eversion of vessel walls during clip placement and a special everting forceps and experienced assistant are needed. In an end-to-side anastomosis, four sutures are recommended with sutures at the heel and toe and two stay sutures at the 3 and 9 o'clock positions. Yamamoto *et al.*⁶⁵ reported clinical use of these staples with a mean anastomosis time of 12 minutes and Cope *et al.*⁶⁶ reported a 100% patency rate of 153 anastomoses of both veins and arteries. A comparative scanning electron microscopic study demonstrated no major differences between sutured and stapled anastomoses.⁶⁷

All anastomotic devices are essentially for use on healthy vessels only; the veins should be pliable, the arteries soft to allow eversion,⁵² and the vessel ends minimally size-discrepant.

Other nonsuture methods

Methods to glue or to weld a union of two vessels seem attractive and have been intensively studied experimentally.

Two adhesives have been studied for use in anastomoses: fibrin glues, and cyanoacrylate glues. To prevent the glue entering the vessel lumen, it was essential first to approximate the vessel walls with conventional sutures, thereby reducing the total number of sutures required for an adequate seal. Fibrin glue is now commercially available as two components, one with fibrinogen, factor XIII, and plasma proteins and a second with thrombin, aprotinin, and calcium chloride. When mixed together, it imitates the final pathway in coagulation. Fibrin glue has been used to seal anastomoses, both experimentally⁶⁸ and clinically.^{69,70} In a comparative study of fibrin glue in free flaps,⁷¹ the application of fibrin glue reduced the number of sutures required to complete the anastomosis and significantly reduced the anastomotic, but not ischemic, times with a slightly lower survival rate in the suture-only group. Although these demonstrate a faster union without compromising patency rate,^{70,71} fibrin has not achieved clinical popularity, partly because of concerns that glue might inadvertently enter the vessel lumen, and the potential for allergic reactions and anaphylaxis.⁷²⁻⁷⁴ Cyanoacrylates have been used experimentally, but have been plagued by findings of histotoxicity,⁷⁵ marked foreign-body granulomatous response, extreme thinning of the vessel wall, splitting of the elastic lamina, and calcification of the media.^{76,77} 2-Octyl-cyanoacrylate, however, might be less toxic.^{78,79}

Welding with thermal^{80,81} or laser⁸² energy has long been advocated but, despite intensive experimental investigation, its clinical application remains scarce. There are no clinical reports of thermal welding to date. Different laser types (neodymium:yttrium-aluminum-garnet,⁸² carbon dioxide,^{83,84} argon and, most recently, diode lasers^{85,86}) have been used, showing up to 100% patency rates and better blood flow in veins when compared to conventional suturing techniques. Laser-activated protein solders have been introduced to achieve more strength.⁸⁷ In an experimental setting, a diode laser-assisted carotid artery end-to-end microanastomosis provided an equal survival rate as a contralateral suture anastomosis, with a shorter anastomosis time, and scanning electron microscopy showed faster healing on the laser side.^{86,88} Although later studies have shown promising results on tensile strength, the fear of possible weakening at the site of the anastomosis with consequent pseudoaneurysm formation has so far prevented the clinical use of laser welding. In a study of 27 patients with laser-assisted microvascular anastomosis, there was a 96.6% overall success rate with one rupture of the arterial anastomosis and three hematomas requiring surgical evacuation.⁸⁹

Other experimentally studied methods of anastomosis have included cylindrical or T-shaped intravascular stents.^{90,91} An external metallic ring has been suggested to keep the cylindrical form of a sutured anastomosis and to avoid through-stitching.⁹²⁻⁹⁴

perform 100%-patent microanastomoses is the first step on the road to becoming a competent microsurgeon.

The working environment

The prerequisites of good microsurgical work are a calm disposition and patience. The surgeon must be able to concentrate on the procedure without unnecessary interruptions and should not be hurried. It is inadvisable to work too long at a stretch and it is perfectly justifiable to take a break during long sessions under the microscope or when using surgical loupes. Undoubtedly, the presence of a competent assistant and a knowledgeable specialized scrub nurse makes a big difference to the speed and ease of the operation. However, it is not uncommon for microsurgeons to operate late at night, alone, or on challenging vessels. Therefore, endurance and perseverance are virtues.

Training

"Some are born microsurgeons while others become so through discipline and training."

Because of the inherent complexity and the increased dexterity and hand-eye coordination required, the traditional apprenticeship model of surgical training cannot be as readily applied to microsurgery; and a special microsurgery apprenticeship in the form of fellowship becomes a must.

Although trainees can learn the techniques from senior surgeons in a clinical setting, training should ideally begin in the laboratory,^{95,96} with novices starting by familiarizing themselves with instrument handling under magnification, progressing from suturing stretched surgical gloves⁹⁷ or silicone tubes⁹⁸ and then to live anastomoses in a rat model.⁹⁹⁻¹⁰² Then in the clinical setting, trainees are usually given the opportunity to do the second vein first, and after achieving a steady patency, the arterial anastomosis can be handed to them under supervision. It is only when they can do both the vein and the artery well under supervision over multiple times that they can be left on their own. Challenging conditions are left to the more experienced members of the team.

Planning and positioning

In surgery, time spent planning and positioning is never wasted and this is especially true for microsurgery. In the right position, movements will be easier and the procedure will progress faster. It is important to be comfortable as comfort often relates directly to success,³⁷ while poor planning and positioning result in fatigue, frustration, and even failure.

Choosing the right incisions and the right positioning of the patient becomes easier with experience. A two-team approach can reduce the operating time and proper patient positioning alleviates the need to reposition the patient during surgery.

The surgeon should position him- or herself comfortably. If seated, preferably on a self-adjustable stool, legs should be under the operating table with feet flat on the ground. This provides a stable base that can be maintained for prolonged periods of time. The forearms should rest on folded drapes such that they are approximately at the same level as the anastomosis. These small details will minimize tremor and fatigue.

General principles of microvascular surgery

Success in microvascular surgery is multifactorial. Of the many factors attributed with success, technical skills in vessel anastomosis are a must-have craft, and learning how to

Next the microscope should be positioned so that it does not obstruct movement, while providing maximum control and maneuverability. However, the location of the anastomosis often dictates where the microscope is ultimately placed. The microscope base is then fixed to allow the surgeon sufficient room to maneuver the microscope into the exact position.

Securing the flap or flap inset

The inset of the flap should be considered before the anastomosis is performed. After circulation is restored, the flap swells and bleeds from the edges and this can make inseting the flap in deep recesses particularly difficult. This is especially true in head and neck surgery where the flap may be required in tight, hard-to-reach areas with limited visibility. The inset should be performed first, ensuring that good hemostasis has been achieved before the pedicle is divided after flap harvest. Partial or complete inset of the flap before the anastomosis also allows for a more accurate judgment of pedicle length, avoiding problems resulting from tension or redundancy. Tailoring or thinning the flap, however, is better performed while the flap is perfused either before pedicle division or after the microanastomoses to allow better control of bleeders and avoid hematoma. In some cases, such as in breast surgery, where the anastomosis lies deep to the inset, there is no choice but to inset the flap after the anastomosis is completed. In such instances, the flap is just secured near the defect, allowing adequate exposure and positioning of the vessels.

Selection and dissection of recipient vessels

Another important factor in ensuring success of free-flap surgery is the use of healthy recipient vessels of appropriate size with good outflow. Ideally they should be away from zones of trauma and sites of irradiation. A healthy vessel has a soft wall and a vascular sheath that can be easily dissected, while traumatized vessels may be encased in fibrotic tissue which is prone to bleeding during dissection. It is sometimes necessary to assess the presence and quality of the recipient vessels, particularly following irradiation and stiff neck phenomenon, lower extremity trauma or in patients with long-standing diabetes or atherosclerotic disease before flap harvest. Preoperative angiography is indicated whenever in doubt regarding the availability or quality of recipient vessels; for instance, if one or both pedal pulses are not palpable or audible by Doppler in the setting of previous trauma. However, it might not add relevant information if at least one pedal pulse is palpable,¹⁰³ and normal findings may not always translate into healthy usable vessels.

For free flaps to the extremity, clinical suspicion of vessel damage, ankle/brachial pressure index, systolic toe pressure, and hand-held Doppler auscultation may determine the need for formal angiography. Other considerations in deciding which recipient vessels to use include a single-vessel leg, multiple previous free flaps, and the availability and adequacy of recipient veins.

In head and neck reconstruction, multiple free flap reconstruction, irradiation along with frozen neck, severe atherosclerosis with peripheral artery disease, complicated osteoradionecrosis may all justify further angiographic studies.

Once the recipient vessel has been adequately exposed and identified, dissection of the vascular pedicle proceeds under loupe magnification to free sufficient length to allow a tension-free anastomosis. The total length of dissection ultimately depends upon the length of the chosen flap's pedicle, depth at which the recipient vessels are situated, the size of the vessels, and the technique of anastomosis to be used. Vein grafts have been shown to reduce success rates and can usually be avoided if proper preoperative planning has been made. If the recipient vessels are deep, for example the internal thoracic vessels in breast reconstruction, a greater length of vessel needs to be dissected in order to orientate them in a more desirable position or even more superficially to allow an unobstructed view that will facilitate the anastomosis (Fig. 24.1). Gross trimming of the adventitia is performed around the area of the anastomosis, allowing sufficient length of trimmed vessel for application of the vascular clamp. The

Fig. 24.1 Horizontal vessel orientation allows both lumens of the vessel to be adequately visualized.

quality of the artery and vein must then be checked. Under microscope magnification, the vessels are inspected for signs of damage that indicate the need for more proximal dissection.

It is vital to check the flow within the artery. Expansile pulsation of the vessel usually indicates adequacy but should be confirmed by healthy spurting from the divided vessel. If a healthy-looking vessel does not spurt well, check that the patient is normotensive. Steps to relieve vasospasm should be taken and are discussed later in this chapter. If there is still no relief, the vessel should be cut back until healthy spurting is encountered. Once this is confirmed, a vascular clip can be applied while waiting for the flap to be harvested or to be inset.

The ideal recipient vein should be at least as wide as the flap vein. If the recipient vein is smaller in diameter, it may produce a bottle-neck effect and compromise drainage of the flap. The vein is divided to assess its quality and good backflow from the vein indicates a fairly healthy vessel. If there is any doubt, a small catheter may be introduced into the lumen and heparinized saline flushed into the vein. If there is little or no resistance, the vein is likely to drain well. If high pressure is required to flush the vein, tying off tributaries near the site of anastomosis may help reduce the backflow. A single or double clamp is then applied in preparation for anastomosis.

The vessels should be irrigated during and after dissection with heparinized saline and, on completion of the dissection, it is common practice to cover the vessels with 2–4% lidocaine or 3% papaverine-soaked gauze pieces to prevent desiccation and vasospasm.

When the flap is ready for revascularization, the vessel ends to be anastomosed are placed in a double approximating clamp under microscope magnification. An appropriate-sized clamp is chosen to allow an adequate length from both vessels between the two clamps. This allows the vessels to be manipulated so that the lumen and intima of both can be clearly visualized whilst allowing the needle to be easily maneuvered. Moist gauze placed beneath the vessel setup is a useful way to elevate the plane of anastomosis and orientate the vessels into a horizontal lie to aid the anastomosis. It also serves as a wick to mop up any pooling fluids that may hinder the anastomosis. And, a silastic tube attached to a suction system and introduced to the microanastomosis site covered with moist gauze can further facilitate drainage without the risk of sucking the anastomosed vessels. Pliable nonadherent and nonreflective background material is placed under the vessels and clamps. If the clamps will not lie flat, a moist gauze piece is usually sufficient to weigh them down and keep them in position. Four moistened gauze pieces are placed around the vessel and clamp to prevent the suture from adhering to surrounding structures. Good hemostasis should be maintained at all times. Even a small but constant trickle of blood will obstruct the working field, decrease flap perfusion,¹⁰⁴ and potentially results in spasm and causes thrombus formation and anastomotic failure.

Preparation of vessels

The lumens of the vessels must be inspected for irregularities such as intimal tears or separation from the media, thrombi, atherosclerotic plaques, and friable calcified walls (Fig. 24.2).

Fig. 24.2 Loose intima.

Fig. 24.3 Intraluminal irrigation of vessels.

Any debris is gently irrigated away (Fig. 24.3) or atraumatically removed with microforceps. Failing this, the vessel should be cut back, without compromising the flap pedicle length, to attain a healthier vessel segment. Occasionally, a suboptimal vessel intima has to be accepted and a successful outcome is then dependent on meticulous anastomotic technique. Some surgeons will choose to cut the vessel back to a healthy level at the expense of length, opting to use an interpositional vein graft in such situations since inadequate debridement of vessels is often a major cause of flap failure.

The vessel wall consists of three principal layers. The innermost tunica intima is formed by a single layer of endothelium resting on a basal lamina. External to this is a thin subendothelial layer consisting of connective tissue adjacent to the internal elastic lamina that separates the tunica intima from the tunica media. The tunica media consists mainly of smooth-muscle cells and is the thickest layer of the arterial wall. In veins, however, this layer is much thinner and, sometimes in lesser veins, almost indistinguishable. The tunica media is covered by the external elastic membrane, and the outermost layer of the vessel wall is the tunica

Fig. 24.4 Cross-sectional view of artery (left) and vein (right).

Fig. 24.5 Sharp trimming of adventitia.

adventitia. This comprises loose areolar connective tissue that contains the vasa vasorum, which nourishes the vessel wall.¹⁰⁵ Veins consist of the same layers as arteries, but the layers are less defined, particularly with regard to the tunica media which in some lesser veins is almost indistinguishable (Fig. 24.4).

Loose adventitia can be peeled off the vessel wall using microforceps or sharply trimmed by pulling it towards the lumen and cutting parallel to the luminal edge (Fig. 24.5) to a distance of 3–4 mm from the anastomotic site. It has been shown that neither method completely removes all the adventitia and that sharp dissection appears to cause less damage to the vessel.^{106,107} The main purpose is to improve visualization of the vessel ends and prevent the adventitia from falling into the lumen while tying the knot. Alternatively, a more radical trimming is performed by cutting the tented adventitia parallel to the length of the vessel, meticulously avoiding injuring the tunica media (Fig. 24.6). Avoid overly aggressive adventitial stripping as this may cause necrosis of the vessel wall at the anastomotic site with resultant false aneurysms. In

Fig. 24.6 More radical resection of adventitia.

Fig. 24.7 Gentle luminal dilatation of the vessel end.

smaller veins with thin tunica media, it is advisable to remove only the adventitia that overhangs the vessel ends.

The vessel lumens are gently dilated in two different planes with a vessel dilator or microneedle holder and the stretch maintained for a second (Fig. 24.7). This will aid the suturing process, prevent vasospasm, and allow intraluminal blood to

be flushed out with heparinized saline, and overcome minor degrees of size discrepancy. Blood beyond the clamps, in undamaged vessels, is not in contact with wound thromboplastins and is not at risk of clotting. A hemostat artery forceps is used to bring the two clamps towards each other so that the vessel ends are just touching or with minimal overlap (Fig. 24.8).

Fig. 24.8 Using artery forceps to bring the clamps together.

Fig. 24.9 Interrupted suturing techniques by placement of three stay sutures at 120° or at 180° to ease subsequent placement of sutures.

Anastomotic sequence

There is no consensus regarding optimal anastomotic sequence. In reality, the relative vessel position will dictate whether the artery or vein is first anastomosed, with the deeper, more-difficult-to-reach vessel being repaired first.

If the anatomy does not restrict the choice, arterial repair first may be a sensible choice as it will shorten the warm ischemia time. The re-establishment of circulation may also reveal the more dominant venous drainage to aid the selection of which donor vein to use and more importantly to detect any possible twist, kink, or compression in the pedicle, in particular the perforator. There are disadvantages, however, as the flap may start bleeding and affect the anastomosis of the vein. Subsequent venous congestion may increase bleeding from the flap edges and allow a buildup of free radicals. To avoid this, the second vein may be intermittently released to allow drainage of the flap. Alternatively, the venous anastomosis could be performed first, which additionally allows for better adjustment of the pedicle length, although this will delay revascularization of the flap.

An early experimental study showed that flap failure in straightforward cases was highest if the arterial anastomosis was performed first and immediately unclamped. This was attributed to venous congestion.¹⁰⁸ However, other studies have failed to show an optimal sequence of anastomosis in both skin and muscle flaps.^{109,110} In our practice of more than 1000 free flaps per year, we routinely repair the artery first and leave it unclamped as the vein is being repaired and have not noticed major problems related to the temporary venous congestion. If there is a second comitant vein, however, we avoid venous congestion by allowing the less dominant vein to drain freely into gauze away from the operating field.

Some surgeons advocate two venous anastomoses where possible to avoid complications of venous insufficiency, and Khouri *et al.* reported a significantly higher failure rate when only one venous anastomosis was performed (4.3% versus 0% if two anastomoses).¹¹¹ A single venous anastomosis to a suitable recipient vein however will provide adequate drainage and reduce operative time without increasing morbidity. Futran and Stack showed equivalency of single and dual venous anastomosis with respect to flap survival in a series of 43 free radial forearm flaps.¹¹² This too is our clinical experience. Sound judgment is required and, if the first vein is less reliable or if its patency is uncertain, a second venous anastomosis should be performed to secure venous drainage of the flap.

Microvascular anastomosis techniques

Having discussed the general principles of setup, vessel preparation, and common pitfalls, this section now focuses on how these principles can be applied to the different anastomotic techniques to achieve success.

Suturing techniques

End-to-end anastomosis

The method of performing the anastomosis depends largely on personal preference. The end-to-end anastomosis using

Fig. 24.10 Knot tying with a double throw.

interrupted sutures is by far the most common method used. It is simple and appropriate for most arterial and venous anastomoses. A halving, triangulation, or “back wall-up” technique can be used to perform this anastomosis (Fig. 24.9).

Carrel recommended avoiding luminal narrowing at the anastomotic site, avoiding the creation of folds and a rough inner surface of the vessel, and opposing the two intimal edges closely. These principles still hold true today. In his original description,¹¹³ three stay sutures were placed at 120° from each other. Cobbett modified this, using only two stay sutures at 120° from each other, and found that, when tensioned apart, the longer back wall fell away from the shorter front wall and reduced the chance of taking a through stitch, where the intima of the posterior wall is incorporated into the suture. Another alternative to this is placing the two stay sutures at a 180° angle to ensure even spacing between the sutures.

The second stay suture is the most important, difficult one and will determine the technique. The needle should penetrate the vessel wall in perpendicular fashion incorporating all the layers of the vessel, especially the intima. The size of the bite is determined by the thickness of the wall and the suture, and should be maintained throughout the anastomosis. The first throw should be a double one to ensure that it maintains the intended tension (Fig. 24.10), and then two single throws follow to complete the knot. The knots are snugged down by sight and not by feel and should stop when the two vessel edges meet and slightly evert. If the sutures are too tight, small tears in the vessel wall may expose the subendothelium

and allow platelet aggregation and thrombus formation.¹¹⁴ Additionally, sutures that are too tight can damage the media of the arterial wall and if at least a third of the vessel wall undergoes necrosis, re-endothelialization does not occur and occlusion of the lumen invariably follows.^{115,116} Tight sutures may also narrow the anastomosis site resulting in thrombus formation.

Sutures are then placed in between the stay sutures, aiming to place the smallest number of sutures to achieve a leakproof anastomosis, and the approximator clamp is turned over. The back wall can now be sutured by either placing a suture exactly midway between the two existing stay sutures or, with experience, sutures can be accurately placed to complete the anastomosis. As the anastomosis progresses, it becomes increasingly difficult to visualize the lumen and it is advisable to leave the last few stitches untied, leaving the ends loose until the last suture is placed. These sutures are then tied in turn. It is better to leave any apparent gaps alone until the clamp is released and the vessel refills in order to prevent through stitching. If the vessel configuration does not allow the clamp to be turned over, the back wall-up technique must be employed. The first suture is placed posterocentrally and subsequent sutures are placed on either side of the first knot, working around the circumference and spacing them appropriately apart. Once the back wall is completed, the anterior wall can be sutured using the interrupted, continuous, or open-loop suture techniques (Figs. 24.11 & 24.12).

Continuous suturing is a technique suitable for minimally size-discrepant vessels larger than 2 or 3 mm and not only can significantly reduce anastomosis time by nearly half but is more hemostatic¹¹⁷ (Fig. 24.13A). However, there are problems with suture entanglement; the sutures must be placed meticulously and the final tying of the knot must be accurate to prevent purse-string constriction of the lumen. It is advisable to place two or three stay sutures, leaving one suture end long. Starting from the last stay suture, running sutures are placed at regular intervals and tied to the next stay suture. Then the needle is passed under the vessel and the double clamp turned over and suturing continued. This reduces the likelihood of creating a purse-string effect (Fig. 24.13B). With meticulous attention to detail, patency rates of 97.5–100% can be achieved^{118–120} in both veins and arteries and end-to-end and end-to-side repairs.

Open-loop suturing is a technique that combines the convenience of the continuous running suture with the

Fig. 24.11 (A, B) Placing a halving suture may facilitate accurate stitch placement when performing end-to-end anastomosis with interrupted suturing.

Fig. 24.12 Back wall first.

advantages of interrupted suturing technique. First a running suture is performed leaving the loops small enough that they do not flop to the side, or two separate stay stitches are placed and running suture performed in between. The first suture is tied and the suture ends cut short. The next loop is pulled through and tied in a similar fashion and cut, the maneuver repeated until all the loops have been tied (Fig. 24.14). This technique reduces the number of maneuvers and the need to handle the needle constantly after each suture. Maximal lumen visualization is maintained throughout and the risk of purse-stringing is eliminated. This method needs practice, however, as the loops can easily become entangled and time may be wasted untangling them.

Sleeve anastomosis, introduced by Lauritzen¹²¹ in 1978, is a variant of the end-to-end technique, “end-in-end”, and entails telescoping the vessels by using two extraluminal sutures that pull one vessel inside the other (Fig. 24.15). Fewer sutures are required, resulting in reduced anastomosis time and less vessel trauma, but low patency rates reported by Sully *et al.*¹²² prevented this technique from gaining popularity, despite contradictory results by others. The sleeve technique was suggested to be limited to vessels with size discrepancy. A modification of “hemi-invagination” by Riggio *et al.*¹²³ improved patency rates to 95–100% by placing a side cut on the overlapping vessel and adding a stitch at its apex, thus effectively dilating the vessel to facilitate anastomosis of vessels of equal size. However, it was only tested on rats; clinical studies are lacking.

End-to-side

The end-to-side anastomosis is particularly useful when there is significant vessel size or wall thickness discrepancy¹²⁴ or when

Fig. 24.13 Continuous suture. (A) Complete anastomosis using one continuous suture.

Continued

Fig. 24.13, cont'd (B) Using stay sutures placed at 180° and performing continuous sutures between the two and tying off to each stay suture prevents purse-stringing of the lumen. (From Chen YX, Chen LE, Seaber AV, Urbaniak JR. Comparison of continuous and interrupted suture techniques in microvascular anastomosis. *J Hand Surg Am.* 2001;26:530–539.)

there is a need to preserve the distal circulation, as in a single-vessel leg. Anecdotally, end-to-side anastomosis, especially, in lower extremity could be less prone to vessel spasm, associated with higher success rates,¹²⁵ but not necessarily of higher patency rates compared with end-to-end anastomosis.¹²⁶

In order to perform an end-to-side anastomosis, an arteriotomy or venotomy has to be made in the recipient vessel. This may be triangular or elliptical or a simple longitudinal slit that will open up due to contraction of the muscle in the vessel wall. The hole should not have irregular edges as this

Fig. 24.14 Open-loop suture.

may weaken the wall and facilitate thrombus formation. A sufficient length of recipient vessel is dissected to allow placement of two clamps on either side of the anastomotic site and the adventitia trimmed nearly circumferentially between the two clamps. A baby Satinsky clamp is useful for clamping the recipient vessel to facilitate the anastomosis while maintaining the flow and is less traumatic than bulldog clamps. Alternatively, vascular slings may be double-looped around both ends and tightened to act as stabilizers and to cut off the blood flow to the segment of vessel. A single stitch is taken transversely at the anastomotic site and used as a stay suture. Holding this suture up, the vessel around the suture is excised using microvascular scissors and extended as necessary with a no. 11 blade (Fig. 24.16). Alternatively, the Acland–Banis arteriotomy clamp can be used to pick up and hold part of the vessel wall that is to be excised. The blade is then held close against the clamp tip, allowing an ellipse to be excised. Ideally this opening should not be longer than the diameter of the donor vessel as it will stretch once the clamps are released.

Fig. 24.15 Sleeve anastomosis.

Fig. 24.16 End-to-side anastomosis. Making the arteriotomy.

If the flap vessel is long enough, the anastomosis can be performed with stay stitches at the distal and proximal ends of the arteriotomy and the “front” wall can be completed before pulling the vessel towards you and performing the “back” wall as described by Godina.¹²⁵ If there is insufficient length to manipulate the donor vessel, then the wall further from you must be performed first (Fig. 24.17). The sutures are then placed radially to the center of the arteriotomy. Persistent leakage from the distal and proximal ends may be severe if the sutures are placed transversely.

According to Godina, the additional advantages of this anastomosis included a higher success rate, greater freedom of operative planning, and technical simplicity in terms of access to the vessels and it was his anastomotic technique of choice.¹²⁵ However, in a study of over 2000 microvascular anastomoses in more than 900 tissue transplants, end-to-end and end-to-side microvascular techniques were found to be equally effective when properly applied. Patency approached 100%.¹²⁶ Although arterial anastomosis patency was similar to end-to-end anastomosis, end-to-to side venous anastomosis had a higher success rate in a study of 90 rats.¹²⁷ In a further experimental study, while there were no differences in vessel patency between an end-to-side hole and an end-to-side slit technique, the latter was easier to perform in vessels less than 1.5 mm in diameter.¹²⁸

Use of the coupler

The use of the anastomotic coupling device is the most common alternative to the conventional suture. It is a time-saving alternative that consistently produces equivalent patency rates to conventional methods. The outer diameter of each vessel is measured after gentle dilatation against the

Fig. 24.17 End-to-side anastomosis. In cases where there is insufficient length to rotate the vessel, the back wall needs to be sutured first.

vessel-measuring gauge. In size-discrepant vessels, a coupler is chosen such that the internal diameter of the device is the same as the measured outer diameter of the smaller vessel.

The coupling device is loaded on to the anastomotic instrument, ensuring that it is well seated. The anastomotic instrument is placed perpendicular to the vessels, and the vessel end threaded through the ring. The edges of the vessel are impaled securely on to the first pin, taking a bite that is approximately 1–2 pin diameters with an adequate intimal bite. The vessel is impaled on every other pin first before completing the intermediate pin placements to ensure it is evenly spaced. Draping the flap vessel first allows easier position of the coupler than the less mobile recipient vessel. The rings are then brought together by turning the applicator handle clockwise and reinforced using hemostat artery forceps. The applicator handle is turned counterclockwise to eject the device (Fig. 24.18).

Difficult, less commonly encountered microvascular anastomosis

Anastomosis between size-discrepant vessels

Despite careful planning, size-discrepant vessels are commonly encountered. More problems are encountered if the inflow from the recipient is big while the flap artery is small, or if the outflow of the flap is big while the recipient vein is small, compared with the opposite conditions. It is better remembered that sudden change of caliber may still cause turbulence that predisposes to thrombosis. Various techniques are used to deal with this, and vessel mismatches of up to 4:1 can be anastomosed end-to-end depending on the level of technical skills. The simplest method is gently to stretch the smaller vessel mechanically to match the larger one, placing interrupted sutures further apart on the larger vessel. Alternatively, placing a fish-mouth incision or obliquely cutting the smaller vessel

can reduce the discrepancy. Angles of more than 30° of the oblique cut may cause kinking, and should be avoided.

Another technique involves performing the anastomosis just distal to a side branch and opening up the distal wall so that the V shape of the branch is now the vessel end. When the discrepancy is greater than 3:1, consider an end-to-side anastomosis, a vein graft to graduate the discrepancy, or using a side branch of the larger vessel, which may be a better size match. As a last resort, the smaller vessel is dilated maximally and sutured as widely as possible to the larger vessel. The remaining vessel can be directly sutured to itself and an obliquely placed surgical clip will taper the vessel and minimize turbulence (Fig. 24.19).

A discrepancy between the vessel walls may also be encountered but does not usually pose a problem. Gentle dilation will serve to thin the wall but if a significant discrepancy persists, the key is to take equal bites of the intima from both vessels, incorporating less of the media and adventitia of the thicker-walled vessel.

Vertically oriented anastomosis

This is the most challenging configuration of vessels. If possible, change the position of the body part, and adjust your position or table to make the anastomosis more horizontally oriented. Freeing up more of the vessel length will allow the vessel to be manipulated into a more horizontal plane using properly placed gauze pieces. If the position cannot be changed and there is limited space to rotate the vessel, reduce the magnification of the field as this will increase the depth of field, reducing the need to alter the focus of the microscope constantly on each vessel end.

Atherosclerosis and loose intima

Atherosclerotic vessels are commonly encountered given that free-flap surgery is extended to the elderly and those with

Fig. 24.18 Application of the coupler device. (A) The vessel is oriented at 90° to the applicator and the vessel end impaled evenly on the pins. (B) The vessel is anastomosed and released by turning the applicator handle.

Fig. 24.19 Size-discrepant vessels. **(A)** The smaller vessel end can be dilated and stretched to match the larger one, cut obliquely to increase the diameter or a longitudinal side cut of the smaller vessel can be made. **(B)** The smaller vessel can be sutured as widely to as much of the larger vessel. A clip can be brought across obliquely to taper the remaining end of the larger vessel and may help to reduce turbulence.

cardiovascular disease. However, radiotherapy is also responsible for irradiation-induced atherosclerosis,¹²⁹ further increasing the exposure to atherosclerotic vessels in microsurgical reconstruction.

If a significant plaque is found, cutting back the vessel to healthier intima or even choosing another vessel altogether may be necessary. The artery should be divided with sharp scissors in one cut to minimize separation of the atherosclerotic intima. Sometimes atherosclerotic plaques can create a false lumen, or may appear as another vessel wall, and irregularities in these plaques can turn inside the lumen as an intraluminal flap, which may cause thrombosis. Therefore, after cutting the artery, the atherosclerotic plaque should be carefully looked for, and the cut edge should be trimmed using fine scissors. This trimming should be performed slowly

and circumferentially, in a manner resembling opening a can rather than a guillotine cut.¹³⁰

The vascular clamp should not exert too much tension as this can fracture the calcified walls or plaques. So, proper micro-clamp tension should be provided only in areas which are not affected by atherosclerosis, if used at all. One may consider microclamps which are used for venous anastomosis for both the artery and vein, so that less pressure is applied when clamping.

A round needle is useful and meticulous placement of interrupted sutures using the smallest microsuture should be ensured. The intima must be visualized at all times and the suture should ideally be passed from the inside of the lumen of the atherosclerotic vessel to the outside to avoid further separation of the intima from the vessel wall. This is possible

Fig. 24.20 Use of forceps to provide counterpressure to minimize trauma and separation of the intima.

if only one vessel is diseased. But when both recipient and donor are diseased, a double-needle suture may be useful. If unavailable, then careful counterpressure from forceps placed within the vessel as the needle is passed will minimize intimal separation (Fig. 24.20). Vessel dilation should be avoided and careful vessel wall eversion avoids leaving raw areas exposed to the blood flow. Too much tension, however, may erode the plaque and tear the vessel wall.

End-to-end is preferred over end-to-side that usually causes more direct exposure of the atherosclerotic plaque and its edges, resulting in increased risk of thrombus formation.

If end-to-side is unavoidable, as in single vessel-leg, an end-to-end anastomosis is used after providing a T or Y vein graft. However, vein grafts are more prone to thrombosis in these settings and the anastomosis should be finished as soon as possible because prolonged duration may increase the risk of thrombosis, causing long-term blood stasis and exposure with mechanical micro-traumas.¹³⁰

Microvascular grafts

An increased storehouse of flaps with various pedicle lengths, technical refinements, and proper planning has been key to diminishing the need for vein grafts.^{22,131} Despite this, they are still sometimes necessary, particularly in the trauma setting, vessel depleted neck, and re-explorations. There is an association between interposition vein grafting and free-flap complication and failure;^{111,132,133} however this may be a reflection of the complexity of the case and other factors such as vessel quality¹³⁴ and hematoma formation¹³⁵ that can independently lead to flap failure rather than the actual use of the vein grafts. Indeed, other studies have shown that patency and flap survival are not reduced by the use of vein grafts,^{136,137} which can be performed quickly and safely if certain principles are followed.

The indications for vein grafts include a recipient vessel out of the reach of the pedicle or under tension despite adjustments in flap inset or skeletal shortening, considerable size mismatch, and the need to place the anastomosis outside the zone of injury/radiation. Occasionally the judicious use of a Y-shaped vein graft will serve a further function of being able to restore circulation to the distal stump.¹³⁸

The harvest of the graft is just as important as the subsequent anastomosis and should be done with loupe magnification. Ideally, the vein graft should match the caliber of the vessels to be anastomosed.¹³⁹ If possible, upper limb defects are bridged with upper limb veins. The workhorse vein graft is the great/lesser saphenous vein with the advantages of length and two-team approach. Other alternatives include the cephalic and the comitant veins of the free flap. Volar forearm and dorsal foot veins are preferred in finger and hand replantation for size-match and arch-like configuration. All vein grafts need dilatation prior to anastomosis to allow a better wall thickness match. If there is a concurrent lack of soft-tissue cover, a narrow venous flap for arterial gaps may solve both problems at once.¹⁴⁰ The vein should be handled minimally during the dissection and all tributaries ligated or coagulated. The length required should be marked out, remembering that vein grafts contract after division only to lengthen considerably, with the potential risk of kinking, after restoration of high-pressure flow.

Since even short segments of veins may contain valves, the direction of the vein is crucial and must always have antegrade flow. In our practice, the proximal end is marked with a surgical clip. This facilitates hydrodilatation of the vessel which stretches the graft out to length, untwists the vein, relieves vasospasm, and allows visualization of potential bleeding points. The open end is then anastomosed first and the clamp released for a final check that the direction is correct and the length not redundant.

Arterial grafts have significant advantages over vein grafts, such as the absence of valves, an anatomical taper, similar luminal and wall-thickness profiles, and better handling characteristics. Arterial grafts maintain their endothelium and have less subintimal hyperplasia. They also produce more prostacyclin relative to vein grafts in the first 3 weeks, resulting in greater antithrombogenic activity.¹⁴¹ However they have not been shown to have significant advantages in the context of microvascular surgery.¹⁴² They may be harvested from the subscapular tree,¹⁴³ anterior and posterior interosseous arteries,¹⁴⁴ radial or ulnar arteries, the deep or superficial inferior epigastric artery,¹⁴⁵ and the dorsalis pedis artery.

Testing patency

Patency should be assessed after the completion of each anastomosis and the flap assessed for adequate perfusion periodically through the operation. This can be done by simple observation or by conducting a patency test.

The characteristics of the arterial pulsation are important and can be expansile or longitudinal. The latter occurs in the long axis of the vessel and is a sign of partial or complete thrombosis. The flap will show no evidence of return of circulation and the anastomosis should be redone. Other signs of patency of the artery include good flow from the vein. If the recipient vein fills well and has a natural round diameter it is likely to be patent. If it is engorged and the blood column

Fig. 24.21 Empty-and-refill test. (A) Direction of flow across the anastomosis. (B) Two atraumatic forceps are placed downstream of the anastomosis. (C) The forceps furthest away from the anastomosis is used to empty the vessel downstream. (D) The proximal forceps is released whilst the distal one continues to occlude the vessel. The vessel should immediately refill confirming patency.

is darker than that in the recipient vessel, it is thrombosed and will require reanastomosis. Other signs of a nonpatent venous anastomosis will include engorgement of secondary veins within the flap, and continuous dark bleeding from the edges of the flap.

If in doubt, two simple tests can be performed distal to the anastomosis. The first is an “uplift” test by gently hooking up a thin-walled vessel until the column of blood is almost occluded. If the vessel is patent, alternate filling and collapsing with each pulse will be evident. The second is the empty-and-refill test³⁷ (Fig. 24.21). This test is slightly more traumatic and should only be performed when needed, preferably on veins not arteries, to minimize spasm or intima separation. Gently occlude the vessel distal to the anastomosis, and, with a second pair of forceps, empty a segment of the vessel by occluding the vessel next to the first pair and running it in the direction of the flow. The first pair of forceps is released and the emptied segment refills immediately. If the refill is sluggish or absent, the vessel is not patent.

General aspects of free-flap surgery

Although the first clinical application of microvascular surgery was in replantation, this soon evolved into free-flap surgery, bringing about a new era in reconstructive surgery and allowing the reconstruction of previously unreconstructable defects. The concept of the reconstructive ladder and then the reconstructive elevator were introduced as a series of reconstructive options with increasing complexity; this approach to wound management has served us well for the past three decades but not anymore. With the advent of microsurgery, the aim shifts

to treatment regardless of complexity, as technical concerns become reduced. But since more complex wounds are created through more radical surgery, for either tumor extirpation or trauma debridement for which a suboptimal reconstruction is the corollary of classic methods, the best outcomes often cannot be achieved without utilizing microsurgery; this further brings on, in many occasions, single-stage total reconstruction and reverses, as a result, the reconstructive ladder/lift.

Now, it is appropriate to say that with microsurgery, the sky is the limit for reconstructive surgeons; this summarizes what we have achieved thus far and what we are going to witness years from now.

Advantages and disadvantages

The advantages of free microvascular tissue transfers over more conventional methods of reconstruction have been well documented. Free-flap surgery offers freedom of choice of donor tissue components to achieve superior functional and aesthetic results by replacing “like with like”, especially when local or regional tissue is inadequate. The flap can be tailored to meet specific requirements of the recipient site in size, form, tissue components, and even function. In contrast to regional or distant pedicled flaps that may require a multistage reconstruction, the use of free flaps is often a single-stage procedure that allows earlier mobilization and return to work, reduced hospitalization and overall costs. The new tissue has better cutaneous blood flow¹⁴⁶ and vascularity that may enhance wound healing and reduce infection. With an increasing repertoire of flaps and refinements in their harvest, a donor site which can be primarily closed with minimal donor morbidity is favored and can often be used.

When both operation and recovery proceed as planned, the advantages of free tissue transfer are clear. However, these benefits have to be weighed against the risks of long surgery and anesthesia spasm and microvascular thrombosis, re-exploration, and the dreaded complication: flap failure.

Preoperative evaluation

Patient factors

Free tissue transfer is feasible and often successful in the presence of patient factors once considered to be high-risk for flap failure. However, it is important to evaluate fully the fitness of the patient for free-flap surgery to identify and reduce the risk factors associated with poor outcome.

As with all major surgeries, cardiac and respiratory fitness should be optimized before free tissue transfer. This encompasses good preoperative hypertensive and diabetic control. Age, in itself, is not a contraindication to free-flap surgery as long as the patient is in otherwise acceptable health and deemed fit for anesthesia. The outcomes of free tissue transfer in the extremes of ages are comparable to those in the general population,^{111,147-152} although there is an increase in postoperative medical complications in the elderly.

Smoking has not been shown to significantly affect vessel patency, flap survival, and reoperation rates, but increases donor site complications with poorer wound healing at the flap-wound bed interface.¹⁵³⁻¹⁵⁶ However, patients should be advised to stop smoking preoperatively as their risk of complications approaches that of the nonsmoker if they stop smoking 4 weeks before surgery.

Obesity clearly increases the risks of microvascular surgery and is associated with increased hemorrhage and hematomas.¹¹¹ In 936 transverse rectus abdominis myocutaneous (TRAM) flap breast reconstructions, the incidence of total flap loss, hematomas, seromas, and overall donor site complications was higher in patients with a body mass index of over 30.

Alcohol withdrawal is also related to increased flap failure¹⁵⁷ and nonflap-related complications¹⁵⁸ and patients at high risk for postoperative alcohol withdrawal syndrome should be identified and treated prophylactically.

Diabetes mellitus is not an independent risk factor for flap failure, but patients with diabetes mellitus have a 1.76 increased risk of perioperative complications.¹⁵⁹

Liver cirrhosis is a risk factor for perioperative complications. Kao *et al.* showed that complications were high, but the disease severity based on Child's scoring system did not have a statistically significant impact on those complications. However, the risk of postoperative neck hematoma was significantly higher in patients with more advanced liver cirrhosis.¹⁶⁰

Immunosuppression may pose a challenge to free flap surgery. A review of 24 immunosuppressed patients found out that prednisone correlates statistically with operative morbidity, which implies that additional risks of delayed wound healing, partial flap loss, and anastomotic thrombosis should be expected in this group of patients.¹⁶¹ Patients with collagen vascular diseases such as Raynaud phenomenon, systemic lupus erythematosus, and scleroderma have increased incidence for thrombotic events such as deep vein thrombosis; however, they are not at increased risk of micro-

vascular thrombosis or flap failure as long as standard anticoagulant prophylaxis is maintained.¹⁶²

Recipients and donor site evaluation

Irradiation impairs the quality of local tissues and vessels and may predispose to complications at the recipient site.^{163,164} Khouri *et al.* found that reconstruction in an irradiated recipient site was a significant predictor of flap failure, with increased odds of failure of 4.2,¹¹¹ but many others have failed to show that radiation significantly affects flap survival.¹⁶³⁻¹⁶⁵ In our experience of 145 patients with reconstruction in an irradiated field, radiation and time between surgery and radiotherapy had no bearing on overall flap survival but increased the risk of reoperation and complications.¹⁶⁶ Careful dissection and meticulous attention to surgical technique should be undertaken when performing the anastomoses. Where possible, however, site the anastomosis outside the area of irradiation.

Infected or traumatic wounds should be adequately debrided and, if necessary, reconstructive surgery postponed until adequate control of the wound is achieved. The zone of injury needs to be taken into consideration and the anastomosis placed outside this zone where possible. Preoperative angiography or computed tomography angiogram is recommended in patients with abnormal distal pulses,¹⁶⁷ and in those in whom both pedal pulses are not palpable/audible by Doppler.¹⁰³ Normal angiographic findings do not guarantee the presence of vessels suitable for anastomosis, and routine angiography is unjustified.¹⁶⁸

Harvesting a free flap requires an intimate knowledge of the anatomy of the vessels, and their variations, supplying the transferred tissues. The design of the flap may be centered on perforators that are mapped out by a hand-held Doppler device¹⁶⁹ or more accurately through color duplex ultrasound,¹⁷⁰⁻¹⁷² computed tomography angiography with or without three-dimensional reconstruction¹⁷³⁻¹⁷⁵ or magnetic resonance imaging angiograms.¹⁷⁶⁻¹⁷⁸ Accurate preoperative mapping has been shown to aid perforator selection, increase the safety of perforator dissection, and reduce operative time.^{172,175,178}

Choice of flap

Preoperative planning and flap selection and design are more important than the harvest itself. There is no flap ideal for all circumstances and the surgeon must accept some compromises to choose the most appropriate available flap for the patient. Chosen well, the patient comes away with an optimal result; chosen badly, and the entire reconstruction is set up to fail.

The first question to answer is: "Does this defect need a free flap?" If the answer is yes, then other factors to be considered include the size and tissue components of the defect and the goals of reconstruction. For example, for a young patient with a benign tumor of the mandible, in whom functional outcome is as important as aesthetic outcome, a flap that incorporates vascularized bone for immediate or delayed osteointegration of dental implants should be chosen (Fig. 24.22). Conversely, an edentulous elderly patient with a poor-prognosis mandibular cancer and trismus may benefit from a more straightforward operation with a reconstruction plate and soft tissue flap

Fig. 24.22 Osteointegrated teeth in a fibula osteoseptocutaneous flap reconstructed neo-mandible. (A) Segmental defect of the mandible after tumor excision. (B) Double-barreled fibula inset. (C) Final appearance of the mandible after osteointegrated teeth implantations.

with adequate tissue volume such as the anterolateral thigh flap combined with vastus lateralis muscle that addresses the primary goal of uncomplicated wound healing. This approach reserves the potential for secondary optimal reconstruction in cases not suitable for one-stage bony reconstruction.¹⁷⁹ Appropriately sized recipient vessels must be available and must be considered in deciding the length and caliber of the flap pedicle. This may ultimately decide the suitability of one flap

over another in order to minimize the need for interpositional vein grafts.

An important consideration is the potential donor site, such as the cosmetic result of the donor site that requires skin grafting and reduced muscle power and potential herniation following muscle flap and even perforator flap harvest. Consideration should also be given to the logistics of the flap harvest, patient positioning, and the feasibility of using a two-team approach to streamline the operation.

Timing

The timing of post-traumatic lower extremity reconstruction has been the subject of ongoing debate since Godina first recommended that they be performed within 72 hours of injury.¹⁸⁰ Today, when the free flap is actually performed is largely determined by the surgeon's experience and assessment and the local healthcare system, logistics, and facilities. The definitions of the ideal time periods also vary significantly, with some defining acute reconstruction as the interval ranging from emergency or immediate procedures within 24 hours to urgent procedures done within 72 hours, and others suggesting that the first 24 hours be termed "primary free-flap closure."¹⁸¹ There are those who advocate reconstruction within 72 hours^{182,183} or 5 days,¹⁸⁴ but proponents of delaying the reconstruction argue that the viability of an extremity can be better assessed, the reconstructive procedure better planned, and performed under better operating conditions. In our practice, we have found that adequate debridement results in a fresh surgical wound that can be reconstructed at any time and that actual timing has little to do with the final outcome of the flap. However, we agree that immediate cover must be considered if vital structures are exposed and that, on occasion, emergency free-flap transfer may salvage a devascularized limb or a finger, in addition to improving the functional and aesthetic results and shortening the hospital stay.¹⁸⁵ In oncological reconstructions, immediate reconstruction is performed at the same time as the ablative surgery to achieve uncomplicated wound healing. Reconstruction at the same time has been shown to delay the delivery of adjuvant therapy modestly.¹⁸⁶ In reconstruction of the breast, if patients will receive or have already received postmastectomy radiation therapy, the optimal approach is delayed autologous tissue reconstruction after postmastectomy radiation therapy. However, when postmastectomy radiation therapy appears likely but may not be required, delayed-immediate reconstruction, in which tissue expansion is used, may be considered.¹⁸⁷ A recent multicentric study showed a surge in immediate reconstruction rate favoring implant use due to an increase in the proportion of high-risk patients undergoing immediate reconstruction. Interestingly, though, autologous free tissue transfer also increased in the high-risk group but not in the setting of premastectomy radiotherapy.¹⁸⁸

Microvascular anesthesia

The importance of stable anesthesia by an anesthetic team familiar with microsurgery should not be underestimated. Good pain, temperature, and sympathetic control should be maintained throughout to prevent vasospasm and vasoconstriction. Fine-tuning of blood pressure will help in ensuring

that the operation proceeds smoothly; during flap dissection, the blood pressure should be kept adequately low to keep a bloodless field, but brought up gradually when hemostasis is being secured and the anastomosis being performed to ensure good recipient inflow and flap perfusion. Adequate fluid management includes slight hemodilution to maintain high cardiac output and low systemic vascular resistance.¹⁸⁹

Special techniques and flap modifications

Increasing familiarity with the principles and techniques of microsurgery has encouraged various innovations and refinements in the pursuit of excellence. The goal now is not only simply to achieve closure, but to do so with the least amount of donor morbidity, in the shortest operative time, and with the best results in terms of function and appearance.

Endoscopic harvest

Endoscope-assisted harvest of free flaps allows the use of smaller incisions and improved donor site appearance. However this requires special instrumentation and a steep learning curve that may initially increase the operative time. Flaps harvested with endoscope assistance include gracilis,¹⁹⁰ rectus abdominis,¹⁹¹ and latissimus dorsi¹⁹² muscle flaps, temporoparietal fascial flaps,^{193,194} and jejunal segments.¹⁹⁵ Although the complication rates are not dissimilar, incision lengths are shorter, donor site morbidity and pain are reduced, and patient satisfaction is higher when the flaps are harvested endoscopically.

Robot-assisted free-flap surgery

The robot represents the most up-to-date technological innovation in surgery. Its platform can provide high definition 12×–15× digital magnification, broader range of motion, fine instrument handling with decreased tremor, reduced surgeon fatigue, and improved surgical productivity.^{196,197} The role it plays in urologic, gynecologic, cardiac, general, and endocrine surgery is undisputable. However, in reconstructive microsurgery, the application of robots is still preliminary, but not without potential. Transoral robotic surgeries have eliminated lip- and mandible-splitting approaches and allowed the ablation of tumors that have until recently been primarily treated non-surgically.¹⁹⁸ For the robot-created defects, a robot-assisted free tissue transfer could be safely indicated but at the price of prolonged surgery time.¹⁹⁹ Other indications are recipient vessel preparation, in particular the internal mammary vessels for free-flap breast reconstruction,²⁰⁰ and free flap harvest, and the latissimus dorsi, through minimal-access incisions.²⁰¹ Usage in brachial plexus has also been described to improve the surgery.²⁰²

Perforator flaps, free-style flaps, and supramicrosurgery

A perforator flap is defined as a flap based on a musculocutaneous perforating vessel that is directly visualized and dissected free from the surrounding muscle until adequate pedicle length and caliber are obtained (Fig. 24.23). This

minimizes donor site morbidity and allows the harvest of only the specific components required for the reconstruction. In areas where the anatomy of the cutaneous vessels has not been studied extensively or with flaps with considerable variation in anatomy of their blood supply, the detection of an audible perforator with a hand-held Doppler probe may form the basis of flap harvest.¹⁷¹ The vessel is identified at the level of the fascia, through an exploratory incision, and if sizeable (0.5 mm with good visible pulsation), then dissection in a retrograde fashion will follow its course to the parent vessel on which the flap may be raised as a free flap. This concept has been termed “free-style free flaps”²⁰³ and these flaps can be designed almost anywhere as long as small-caliber vessels and small to medium-sized skin paddles are acceptable when pedicle length is not critical.

To reduce donor site morbidity further, Koshima *et al.* advocate supramicrosurgery,^{204–206} the dissection and anastomosis of vessels with diameters of less than 1 mm. This allows flaps based on vessels harvested without breaching the deep fascia, facilitating a quick operative harvest time without intramuscular dissection, but yields a very short pedicle that requires highly honed surgical skills and extremely fine instruments and sutures.

Combined flaps

When the flap consists of diverse tissue components with multiple sources of vascularization, often discrete to each component, the flap is called combined. Based on the physical relationship between the flap components, the combined flap is subdivided into conjoined and chimeric.^{207,208} In conjoined flaps, previously known as Siamese, multiple anatomical territories are dependent due to some common physical junction yet each retains an independent vascular supply.²⁰⁸ In chimeric flaps, on the other hand, there is no physical junction between the territories, perforasomes, components, etc. The conjoined flap has the advantage of providing large surface area while the chimeric allows the freedom of placement of each component and often results in an optimal one-stage reconstruction

Fig. 24.23 Perforator flap harvest via an intramuscular dissection of the perforators. *Perforator. *****Source artery of the perforators: descending branch of the circumflex iliac artery. ----- Edge of the dissected vastus lateralis muscle.

Fig. 24.24 Chimeric flap with muscle and skin component.

of compound defects^{209,210} (Fig. 24.24). Flaps that are microsur-gically fabricated or linked are a subtype of chimeric flap that allows multi-goal reconstruction,²⁰⁸ and they should be considered the “true chimera”. Finally, the concepts of conjoined and chimeric flaps are also applicable to perforator-based flaps.

Thinned flaps

Flaps that are thick and bulky often require a secondary revision in order to improve final outcome. However, with better understanding of the vascular supply and from increasing experience with perforator flaps, one-stage flap thinning has become possible. Skin is nourished by a subdermal plexus arising from branches of the main pedicle in addition to recurrent dermal branches and thinning can be performed safely to about 3–4 mm in thickness in Asians, leaving an unthinned area of 2 cm around the pedicle.²¹¹ This reduces the need for secondary revisions.²¹² Another method of thinning is micro-dissection of blood vessels in the adipose layer under micro-scopic magnification and removal of the adipose tissue surrounding the vessel^{213–215} (Fig. 24.25). The third method that appears promising but still needs further anatomic investigations for wider application throughout the body is to harvest the flap at the level of the Scarpa’s fascia with the superficial circumflex artery perforator flap being the flap of choice for this method.²¹⁶

Prefabricated/prelaminated flaps

Some defects require complex reconstructions of various components that cannot be met by conventional flaps. Flap prefabrication and prelamination have been applied to areas where specific contours and structures are desired, for example, in reconstruction of the esophagus, penis, and certain head and neck defects.

Prefabrication involves a two-stage process, the first of which implants an axial vascular pedicle into the donor tissue that is required,²¹⁷ thus allowing it to be transferable once neovascularization has occurred. The second stage, about 8 weeks after the implantation, involves the transfer of this neovascularized tissue, based on its recently implanted pedicle, to reconstruct the defect on its recently implanted pedicle. This allows the creation of large, thin skin flaps that retain the qualities of the donor site and can be modified with various combinations of vascular pedicles, donor tissues, and geographic locations for different clinical needs.^{218,219}

Prelamination is another two-stage process where one or more tissues are added to a reliable vascular bed to create a multilayered composite flap. In the second stage, once matured in approximately 2 weeks, the composite flap is transplanted to the defect. This delayed procedure allows the best chance for the prelaminating layers to heal, stabilize, and assume their expected structures and positions. By laminating the vascular bed with skin, bone, cartilage, or mucosa, prelami-nated flaps have been used to reconstruct the oral lining,²²⁰ ear,²²¹ nose,^{222,223} neourethra,²²⁴ penis,²²² and trachea and larynx.²²⁵

Postoperative management, complications, and outcomes

The postoperative management of the patient is crucial in preventing major morbidity and mortality. Patients should be kept warm, adequately hydrated (hematocrit <0.3), and pain free. Blood pressure should be normalized based on preoperative blood pressure and tachycardia avoided as sympathetic overdrive may cause vasospasm. Good hyperglycemic control reduces the incidence of complications in the surgical patient who may require insulin therapy. Prophylactic antibiotics are routinely prescribed to prevent wound infection and low-molecular-weight heparin is used to prevent deep vein thromboses.

Monitoring

Monitoring begins on the re-establishment of blood flow into the flap. The flap should constantly be assessed on release of the microvascular clamps, during closure, on completion of inset, when the patient transfers from the table, and on admission into the ward.²²⁶ Early detection and intervention of flap problems can improve overall flap salvage.^{227–229} Although many methods of flap monitoring are now available, none has been completely effective or uniformly accepted. The ideal monitor should be reliable, noninvasive, objectively repeat-able, promptly reactive to blood flow changes, appropriate for continuous monitoring in all types of free tissue transfers, usable for the unskilled, and economically available.²³⁰

There is no substitute for experienced nursing and medical staff, whether in a dedicated intensive care unit or on the general ward. Clinical observation of the flap is the gold standard for monitoring and should be performed at 30-minute

Fig. 24.25 Thinning of a thick cutaneous flap. Image shows the edge of the flap where flap has been excised safely to thin the flap according to requirements.

intervals for the first 24 hours. This can be extended to 1–2-hourly for the next 24 hours, then 4-hourly for the next 48 hours. Signs to be noted are color, capillary refill, turgor, and surface temperature. If capillary refill is not obvious, pinprick testing can be used to observe the color and speed of bleeding. However, this pinprick should just scratch the dermis and not penetrate too deeply and risk injury to the underlying pedicle. This form of monitoring may not be as suitable for flaps in aesthetically important areas. Surface temperature measurement with a surface temperature probe is easy and inexpensive²³¹ and a recorded difference of 1.8°C between flap and control sites is 98% sensitive and 75% predictive of vascular compromise.²³² The trend of the temperature of the flap over time is also a useful guide to the failing flap²²⁶ and temperatures below 30°C are indicative of flap failure.²³³

A hand-held pencil Doppler probe (low-frequency continuous ultrasonography)²³¹ applied on to the flap over a cutaneous perforator location is another method of monitoring. This point should be marked intraoperatively away from the pedicle to prevent false-positive results. An implantable Doppler probe can be used to monitor flaps without a perforator to the skin or buried flaps.²³⁴ This small probe is attached to a polymer sleeve that is placed around the pedicle vessel (most accurate on the vein) adjacent to the anastomosis with a probe lead wire exiting through the incision. This lead is removed by gentle traction which leaves the sleeve in place when monitoring is no longer required. The signals have a characteristic pattern that can differentiate arterial from venous thrombosis. The method is sensitive; however, it has a high false positive rate, resulting in frequent intraoperative maneuvers to amend the cause of signal loss. Some authors even reported on significantly more vascular thrombotic events when compared to the non-flow coupler group.²³⁵ Laser Doppler measures the reflected waveforms of light, from a helium–neon laser, by the red blood cells moving within the capillaries, and provides an objective measurement for flap perfusion. Interpretation of the results of laser Doppler requires experience but can be very accurate, detecting vascular compromise with no false positives or negatives²³⁶ and distinguishing venous obstruction from arterial occlusion.²³⁷

Other available adjuncts less commonly used include pulse oximetry to identify both a pulsatile flow and arterial saturation in replanted or revascularized digits or toe-to-hand transfers,²³⁸ photography, tissue oxygen tension measurement, tissue pH levels, microdialysis, fluorescein dye mapping, near-infrared spectroscopy, thermodilution technology, photoplethysmography, and nuclear medicine studies.²³⁹

In a recent survey of the members of American Society of Reconstructive Microsurgery, a questionnaire concerning perceptions and frequency of use of several technologies in varied clinical situations revealed that hand-held Doppler was the most commonly used technology; however, surgeons were more willing to opt for immediate take-back to the operating room based on concerning findings of tissue oximetry compared with concerning Doppler signals.²⁴⁰ This suggests that of all available adjunct technologies, tissue oximetry may have the greatest impact on clinical decision-making in the postoperative period.

Nevertheless, clinical monitoring remains the gold standard and, regardless of which adjunct is additionally used, close flap monitoring should be a standard part of the

postoperative care of these patients during the first 72 hours after surgery at the minimum.

Telemonitoring

The clinical inspection remains the gold standard in free flap monitoring; however, it necessitates that the decision-maker evaluates the flap him/herself to decide on take-back to the operating theatre or “close eye-on” approach. To enhance communication and make clinical inspection friendly yet efficient, smart phones can be used. These carry-on devices when integrated in flap monitoring showed comparable accuracy rate but shorter response time compared with in-person examination,²⁴¹ which may increase salvage rate and overall flap success rate,²⁴² making the combined use of smart phones and internet appealing and invaluable in the modern era of digital technology.

Buried flaps

Monitoring buried flaps postoperatively is a challenge and many techniques have been used to assess the flaps, either directly or indirectly. Implantable Doppler probes have been used routinely, as covered previously. However, due to high sensitivity and positive-negativity, it could now be utilized as a screening tool and a color Doppler can be used to confirm the findings or avert unnecessary surgical exploration.²⁴³ Alternatively, color Doppler ultrasound can verify normal arterial and venous flow through the pedicle, as demonstrated in a functioning muscle transfer study.²⁴⁴

Part of the flap may be externalized. For example, a jejunal stump may be brought to the surface to observe peristalsis and color or a skin paddle may be externalized. This should be used with some caution as this only monitors the common source vessel and may not accurately reflect the buried component, especially if the two components are based on different perforators.²⁴⁵ The distal end of the pedicle that is usually ligated close to the supply of the skin can also be externalized and its pulsations observed directly under a transparent film dressing. This can then be tied off in the follow-up clinic.²⁴⁶

Flap outcomes

With maturation of microsurgical technique, failures have thankfully become rarer and success rates of free tissue transfers now range from 96% to 100%.^{22,66} Failures can be attributed to poor planning, poor choice of flap or vessels, poor timing, or poor technique. However, many of the failing flaps may be salvaged and the success of the salvage (54–100%¹¹¹) is in part dependent on good patient management, highly trained staff, and early detection and intervention.

When a flap begins to fail, the likely causes must be identified and rectified. Although the majority of the complications are related to vascular compromise, simple measures should be taken by the bedside first to avoid unnecessary explorations. Systemic factors such as hypotension, hypovolemia, hypothermia, and sympathetic overdrive due to pain should be resolved. Once the blood pressure is normalized and the patient warmed up, the flap should be reassessed for the need to return to the operating room. Local factors include the release of external compression secondary to compressive surgical dressing, hematoma, or a tight wound closure. Releasing some sutures or loosening the dressings may relieve

the compression, solving the problem or at least temporizing the immediate threat to the flap before the formal salvage procedure. If the flap does not improve, a bedside exploration of the vessels can be performed to relieve vessel twist or kink, to assess the patency of the microanastomosis, and to open the pedicle second-vein to resolve ongoing congestion. After that, a prompt return to the operating room is mandatory in the evidence of thrombosis. Resection and reanastomosis or the use of a Fogarty thrombectomy²⁴⁷ may be required. Intraoperative lysis with urokinase or tissue-type plasminogen activator may also help.^{248–250}

Causes of a failing flap

Anastomotic failure

There are many causes of anastomotic failure, such as those related to technical errors in the anastomosis, or intrinsic factors predisposing to vasospasm or thrombogenesis.

The principal faults leading to anastomotic failure are tearing, leaking, narrowing of the lumen, through-stitching, and inclusion of the adventitia.³⁷ Tearing occurs when there is too much tension at the site of the repair. It can also be caused by too meticulous stripping of adventitia: the veins of the head and neck region are especially fragile. Leaking occurs when there is too big a gap between sutures, or there is a tear or a tiny unnoticed branch near the anastomotic site. Even a small leak will precipitate intraluminal thrombus formation²⁵¹ and narrowing of the lumen can also be caused by oversized bites, entangling knots with one another, or continuous suturing that is too tight. Through-stitching entails taking a bite of the back wall with the suture, causing luminal obstruction. This can be avoided by always visualizing the lumen of the vessel through constant luminal irrigation by an assistant or by raising the anterior wall with the tips of microforceps to separate it from the back wall. Inclusion of adventitia as a result of inadequate vessel preparation should be avoided as the prolapsed adventitia is another nidus for thrombus formation. Finally, desiccation of the vessel may also lead to failure.

Vasospasm

Vasospasm occurs in 5–10% of microsurgical procedures and plays an important role in the pathogenesis of hypoperfusion, promoting thrombosis, which may lead to partial or total flap loss. It may be seen intraoperatively and up to 72 hours postoperatively, with the former often being more problematic. The pathophysiology of vasospasm is not clear, but is thought to occur secondary to both general and local factors. General factors include low core temperatures, hypotension, and sympathetic response to pain, while local factors include trauma to the vessel, tight adventitia, myogenic response to local hemorrhage, desiccation of the tissues, and vascular disease. Surgical dissection may induce sympathetic nerve endings to release vasoactive compounds, and impair release of vasodilators,²⁵² compounding the vasospasm and thrombosis. Veins appear to be less susceptible to vasospasm than arteries but, once established, harder to resolve²⁵³ and more detrimental.

If the vessel is left untouched for a few minutes, it may vasodilate to its natural diameter. However, a variety of antispasmodic agents or mechanical dilation can be used to aid relief of the vasospasm.

Most of the antispasmodic agents available are locally applied to avoid systemic complications. The most commonly used agents are papaverine, lidocaine, and calcium channel blockers such as nifedipine, verapamil, and nicardipine. Papaverine (30 mg/mL) is an opium alkaloid that functions as a phosphodiesterase inhibitor and has a direct action on smooth muscle through the release of cyclic adenosine monophosphate. Lidocaine is a local anesthetic agent that has a biphasic response with low and high concentrations potentiating contraction and dilatation, respectively.²⁵⁴ Its vasodilatory mechanism remains unclear but is thought to be related to sodium–calcium exchange pump. Some studies suggest that its concentration should be increased up to 20% or be combined with papaverine.²⁵⁵ The benefit of lidocaine continues after the drug is washed out with heparinized saline solution and, as it is not significantly absorbed from the wound, systemic effects are unlikely.²⁵⁶ In practice, however, common concentrations of lidocaine used vary between 2 and 4%.²⁵⁷ Calcium channel blockers work by blocking voltage-gated calcium channels in vascular smooth muscle. This blocks the calcium influx required for muscle contraction and may even be more effective than papaverine.²⁵⁸ Sympathetic blockade using brachial plexus blocks has also been reported to be effective.^{259–261}

Mechanical treatments of vasospasm include gently dilating healthy vessel ends with a specially designed blunt-ended vessel dilator forceps or with microneedle holders. Metallic standard-sized dilators or intraluminal irrigation through the passage of a fine intracath may also be used. This should be done with caution, especially in arteriosclerotic vessels, as catheters can strip endothelium and expose the thrombogenic subendothelium.²⁶² Surgical stripping of adventitia is an effective method of relieving vasospasm because of a sympathectomy effect and mechanical thinning of the vessel walls allows them to dilate more freely.²⁶³ If the spasm is intractable, the vessel should be aggressively resected until normal vessel is reached. Occasionally this may require an additional vein graft or turning to another recipient vessel for anastomosis.

Stable and thorough anesthesia is an important requirement: hypovolemia, pain, and low core temperature (<36°C) can all result in vasospasm. The patient's temperature should be constantly monitored and adequate hydration maintained, and the wound should not be allowed to dry out.

Thrombogenesis

Many free-flap complications relate to pedicle thrombosis (4–80% within the first 48 hours) caused by changes in the intraluminal blood flow, endothelial damage, and the state of coagulability. Changes in flow can be due to external mechanical compression from bandages, closure of the wound under tension, the weight of the flap, tension, twisting, kinking, or vasospasm of the vascular pedicle after the anastomosis is completed. Intraluminal turbulence may be caused by irregularities in the intima from technical error, suture material, and the result of size mismatch.

Hypercoagulability may be systemic or local. Hypercoagulable states such as pregnancy, active cancer, and recent trauma should be identified preoperatively as far as possible and warrant thromboprophylaxis. Hypercoagulation disorders like activated protein C,²⁶⁴ hyperfibrinogenemia,²⁶⁵ antiphospholipid syndrome,²⁶⁶ and reactive thrombocytosis²⁶⁷

should be treated preoperatively, although routine screening for these is not cost-effective. Thromboplastins are soluble in water and present in abundance in the surgical wound. When blood is contaminated by this, clotting will occur and periodic irrigation with heparinized saline will minimize this risk. Even a smooth and streamlined microvascular anastomosis will produce some thrombus, and when blood flow is restored, the thrombus continues to grow for 5 minutes, starts to disintegrate by 10 minutes, and disappears nearly completely by the end of an hour. If the anastomosis is irregular, the thrombus will grow rapidly and occlude the vessel. Endothelial cells are critical in local blood flow control and produce vasoconstrictors such as endothelin-1^{268,269} and vasodilator substances, nitric oxide and prostacyclin. Damaged endothelium produces a highly thrombogenic state, resulting in platelet aggregation and the initiation of a complex clotting cascade, and surgical precision is vital to minimize vessel damage.²⁷⁰

The risk of thrombosis is greatest within the first 48 hours and decreases to 10% after 72 hours.²²⁹ Arterial and venous thrombi present at different times and form through different mechanisms. The majority of arterial thromboses occur during the first 24 hours and are related to platelet aggregation at the anastomotic site.²⁷¹ Venous thrombosis is more often responsible for flap compromise, presents later, and is related to the formation of a fibrin clot. The goals of anticoagulant prophylaxis are therefore to interfere with platelet function and aggregation, counter the effects of thrombin on platelets and fibrinogen, and reduce blood viscosity or increase blood flow.²⁷² While the use of anticoagulants to lower the incidence of anastomotic thrombosis is widely practiced, literature regarding the efficacy of one treatment over another is sparse and largely based on the individual surgeon's preference and preconceptions. Protocols differ not only in the agents used, but also the dose, combination, timing, and duration. Heparin, dextran, and aspirin are the most commonly used prophylactic antithrombotics today.

Heparin reduces platelet aggregation, activates antithrombin III (thereby directly deactivating clotting factors II, IX, X, XI and, indirectly, factors V and VIII), lowers blood viscosity, and has direct vasodilatory properties.²⁷³ This polyglycosaminoglycan was the first anticoagulant described and has been in clinical use for over 50 years to prevent both arterial and venous thromboses, even at subtherapeutic levels²⁷⁴ and independent of rate of blood flow. As a washout solution, it may have a protective effect against ischemia/reperfusion injury through a direct effect on microvascular endothelium.²⁷⁵ Intravascular heparin improves flap salvage rates²⁷⁶ and clinically reduces the rate of thrombotic events.¹¹¹ Its use, however, may be more important in patients with atherosclerotic or injured vessels, when vein grafts have been used and with thrombosis of an anastomosis, than in patients with healthy vessels and straightforward anastomoses.²⁷⁷ The use of intravascular unfractionated heparin may increase the risk of hematoma formation,^{278,279} but both Chien *et al.*²⁸⁰ and Kroll *et al.*²⁸¹ have found that flap survival was equivalent to that with other regimens without increased incidence of hematoma. Low-molecular-weight heparins, which inhibit clotting factor Xa with less of an effect on thrombin inactivation, may be just as effective in improving patency without the risk of hematoma formation.²⁸² Unfractionated heparin is used universally to irrigate vessels during microvascular surgery and has been shown experimentally to improve patency when

administered at high concentrations^{44,283,284} while minimizing the systemic complications. Heparin binds to the endothelium and has a half-life of 5 hours²⁸⁵ and should be applied as soon as the vessels are divided. Clinically, however, Khouri showed no increase in patency regardless of concentration¹¹¹ and Yan suggested that high-pressure local irrigation might even cause intimal and endothelial damage.²⁸⁶ Nevertheless, together with another important side effect of heparin-induced thrombocytopenia, systemically administered heparin should be used judiciously.

Dextran is a polysaccharide synthesized from sucrose and produced synthetically as a 40- or 70-kDa molecular weight polymer. Its antithrombotic effect is mediated through increasing the electronegativity of erythrocytes, platelets, and endothelium and therefore platelet aggregation, decreasing factor VIII-Ag and thereby platelet function and fibrin structure, and, finally, as a volume expander that reduces blood viscosity. Dextran-40, the more popular dextran for anticoagulation in microsurgery,^{111,281,287} is excreted more effectively by the kidneys and has a shorter action than dextran-70. No randomized controlled studies have shown a cause-and-effect relationship between the use of dextran and flap loss or prevention of thrombosis. In particular, it has not been shown to be more effective than other anticoagulants and its benefits of improved vessel patency are not seen beyond a week.^{288,289} Although it has relatively few side effects, these can be serious and include anaphylaxis, volume overload, pulmonary or cerebral edema, platelet dysfunction, and even acute renal failure.^{290,291} A comparison of dextran and aspirin-related complications in head and neck patients with free-flap reconstructions showed that both were equally effective in preventing flap failure, but dextran was associated with a 3.9- and 7.2-fold increased relative risk of systemic complications after 48 and 120 hours of dextran infusion, respectively.²⁹²

Aspirin is an antiplatelet agent that inhibits cyclooxygenase and reduces the breakdown of arachidonic acid to thromboxane, a potent vasoconstrictor and platelet aggregator, and prostacyclin, a vasodilator that inhibits platelet aggregation. Low-dose aspirin (75 mg/day) has been shown to inhibit thromboxane selectively at the site of the anastomosis²⁹³ while preserving prostacyclin production of the endothelium. Experimentally, it has been shown to improve anastomotic patency and capillary perfusion and may be related to the timing of administration.^{294,295} It is, however, less effective than heparin^{295,296} and, despite the lack of clinical evidence for its effect on free-flap patency, it is still used widely. The adverse effects of aspirin such as gastric hemorrhage, renal failure, and prolonged bleeding are a direct result of the mechanisms that make its use attractive in microsurgery and have been minimized with the use of low-dose aspirin. The newer cyclooxygenase II inhibitors are also associated with fewer renal and gastric side-effects but do not prevent platelet aggregation and are therefore not used in microsurgery.²⁹⁷

Prostaglandin E1 is known for its application in peripheral arterial occlusive disease. It has long-standing anti-ischemic and tissue-protecting effects against ischemia-reperfusion injury. It is capable of relieving microvascular spasm and increases deformability of red cells; in addition to the positive impact on blood flow, viscosity, and platelet aggregation.²⁹⁸ Thrombotic diathesis can be reduced by using a low dose in arterioles, or a high dose in venules.²⁹⁹ It is commonly used in replantation, toe-to-hand microsurgical transplantation, and

other free flap transfer. Despite the promising results reported earlier, a large study analyzing whether prostaglandin-E1 (PGE1) and dextran-40 can improve the outcomes compared to no-antithrombotic therapy in head and neck reconstruction revealed no significant difference among PGE1, dextran-40, and control group in flap survival.³⁰⁰ Other antithrombotic agents tested in animal models to determine their efficacy in augmenting flap survival include pentoxifylline,³⁰¹ hirudin,²⁸⁴ nonsteroidal anti-inflammatories,^{302,303} other antiplatelets such as dipyridamole and ticlopidine.³⁰⁴

Thrombolytics such as streptokinase, urokinase, and tissue plasminogen activator have been advocated for flaps not responding to standard salvage techniques²⁴⁸ and may be effective in reversing microvascular thrombosis,^{249,250} but clinical evidence is sparse and anecdotal.³⁰⁵⁻³⁰⁸ A retrospective multi-institutional study even reported no significant improvement in patency with the use of thrombolytic therapy in free-flap salvage.³⁰⁹ Streptokinase enhances the conversion of plasminogen to plasmin with subsequent fibrinolysis, whilst urokinase and tissue-type plasminogen activator, which activate plasminogen directly, are less antigenic and have fewer systemic effects. There is a significant risk of bleeding following systemic exposure to thrombolytics but this can be minimized by local intra-arterial administration of the thrombolytic and drainage of the venous effluent.³¹⁰

When surgical and pharmacological salvage fails, medicinal leeches (*Hirudo medicinalis*) have been used effectively to treat venous congested flaps.³¹¹ When applied to the flap, they bite into it, injecting a local anesthetic, vasodilator, and anti-coagulant, hirudin, which is present in their saliva. Leeches increase perfusion within congested flaps by feeding on the blood. They then fall away when full, but the bleeding continues for up to 10 hours with the combination of vasodilator and anticoagulant.³¹² New leeches can be applied when the bleeding slows or the flap appears congested again. Therapy is continued until the flap re-establishes an effective venous drainage through new vessel ingrowth around the flap margins. As there can be significant blood loss with leech therapy, this is usually limited to small- to medium-sized flaps and the patient's hemoglobin should be monitored daily. Prophylactic antibiotics should also be given against *Aeromonas hydrophila* from the leeches' digestive tract.

Ischemic tolerance, ischaemia-reperfusion injury, and no-reflow phenomenon

Prolonged periods of warm ischemia (the time between interruption and re-establishment of the circulation) concern microsurgeons as they predispose to tissue necrosis and flap failure. Primary ischemia occurs when the anastomosis is being performed and can be kept to a minimum by donor site and vessel preparation before flap pedicle division and an accurate anastomosis, whilst secondary ischemia occurs later as a result of pedicle obstruction.

The tolerance to ischemia varies from tissue to tissue depending on their metabolic requirements, with skin, nerve, bone, muscle, and then intestine being decreasingly tolerant. Within a composite flap, the overall tolerance is equal to that of the least tolerant component. A study of 700 free flaps failed to show a statistical difference in ischemic times between successful and failed flaps and concluded that ischemic time was irrelevant to flap survival provided ischemia was not

prolonged beyond 3 hours or to the point of "no-reflow phenomenon".

While the goal of microsurgical anastomosis is to restore flow and reperfuse the flap, after a prolonged period of ischemia, this reperfusion may compound insult to the flap through local and systemic inflammatory responses. This is known as ischemia-reperfusion injury and is thought to be a result of the buildup of oxygen radicals during the ischemic period. These cause tissue injury, specifically of cellular membranes through their powerful oxidizing and reducing potentials. They also stimulate an intense inflammatory reaction by recruiting inflammatory cells such as leukocytes, neutrophils, and platelets, and other inflammatory mediators and cytokines,³¹³ while suppressing protective molecules such as nitric oxide synthase, prostacyclin, and thrombomodulin. In clinical free flaps, a similar pathophysiology was also found. From a histological and molecular point of view, significant up-regulation of inflammatory parameters, in particular interleukin-1 β and tumor necrosis factor α , infiltration of inflammatory cells, and angiogenesis were documented. Increased complement component 3 deposition and apoptosis of cells were accompanied by interstitial edema as indication for a pronounced postischemic inflammatory reaction within the muscle tissue after free tissue transfer.³¹⁴ In cutaneous flaps, a significant decrease in total hydrophilic antioxidant capacity (TEAC) was seen.³¹⁵ These findings provided insights into some effective treatment modalities to minimize the damage induced by ischemia-reperfusion injury as discussed below.

Severe ischemia-reperfusion injury results in irreversible vasoconstriction, and the resulting inability to reperfuse the flap despite patent anastomoses is known as the "no-reflow phenomenon".³¹⁶ This is a result of ischemia-induced endothelial injury, which leads to cellular swelling, interstitial swelling, exposure of subendothelial collagen, platelet-leukocyte aggregation, reduction in blood flow and, if not rectified, thrombosis and flap failure.

Experimental studies have shown a protective function of intravascular administration of heparin,^{275,317} vasodilators, prostaglandin E₁, nitrendipine and prostacyclin, thrombolytics, urokinase and streptokinase, nonsteroidal anti-inflammatory drugs, and free radical scavengers deferoxamine and superoxide dismutase.^{318,319} Inhibiting the action of selectins, integrins, and intercellular adhesion molecules with monoclonal antibodies to prevent inflammatory cell adhesion may also prevent ischemia-reperfusion injury, but these have not translated clinically.^{320,321}

Clinically, few pharmacological agents have been used and proved promising. One treatment modality aimed at increasing microcirculation within the transverse rectus abdominis muscle flap by continuous IV administration of arginine showed significant improvement in zone IV perfusion.³²² While the other aimed at reducing the inflammatory response and the interstitial edema by applying negative wound therapy on top of the skin grafted muscle flaps with remarkable reduction in interleukin-1 β and tumor necrosis factor α in biopsies.³²³ The last targeted the endothelial dysfunction using statins drawing on their pleiotropic effects,³²⁴ however, a larger study failed to show clear advantages of the statins or other cardiovascular medications in ischemia-reperfusion injury.³²⁵ So, the benefit of statins remain theoretical, and their usage is limited to patients with cardiovascular diseases.

Donor site complications – dependent again on flap choice

Every flap harvested leaves a donor site of varying morbidity; therefore, the benefits of the reconstruction must outweigh its sequelae. The incidence of donor site complications varies between 5.5% and 31%, with early donor problems associated with wound healing (hematoma, seroma, and wound dehiscence).^{326,327} These are more likely in obese patients, diabetics, and smokers. Hematomas may occur with any flap harvest and meticulous hemostasis with a normotensive (for the patient) blood pressure must be performed. Seromas occur when extensive dissections leave large dead spaces, for example, with a latissimus dorsi or deep inferior epigastric perforator harvest, and wound dehiscence occurs with tight closure, which can be avoided with good preoperative planning.

Long-term problems are usually that of poor cosmesis, reduced function, and chronic pain. If the donor site has to be grafted, this causes a significant cosmetic disadvantage and patient dissatisfaction.^{327–330} Suprafascial dissection reduces the size of the donor defect, allows preservation of the superficial nerves, prevents tenting of tendons, and improves skin graft take. This allows a full-thickness skin graft with superior cosmesis to be applied with confidence and reduces potential tendon exposure from delayed healing.^{330–332} Muscle flaps may cause weakness and functional impairment; for example, serratus anterior muscle elevation may cause scapular winging and the TRAM flap is associated with hernia formation.^{333,334} Harvesting vascularized bone may result in impaired function of a fracture-susceptible donor site, requiring troublesome splinting for a prolonged period,^{326,335} and even affecting gait. Cutaneous nerves may be sacrificed, leaving painful neuromas or unacceptable numbness.^{335–337} Temporary or permanent palsies may result from injured motor nerves and compartment syndrome from overzealous closures.³³⁸

Management of failed flaps

Flap failure has profound implications on both patient and surgeon and represents one of the most challenging aspects of reconstructive microsurgery. Despite the increased experience and refinements in microsurgical techniques and perioperative management, a small number of flaps still fail. With the low incidence of flap failure, there are few articles in the literature that address the management of flap failure and no guidelines regarding the best approach to this problem exist.

Many questions are raised immediately when a flap fails. Why did it happen? What defect requires reconstruction? How and when should the defect be reconstructed? These questions invariably form the basis of a systematic approach to the problem at hand and should be considered when managing a failed flap. Analyzing 54 failed flaps, Oliva *et al.*²⁵ recommend that three issues must be considered when the initial flap is declared nonviable – the reasons for failure, the indications for the free-flap reconstruction, and the current status of the resultant wound.

It is important to identify the reasons for the failure as subsequent attempts at reconstruction might be plagued with the same issues and be doomed to fail. If the cause is reversible or preventable, then this bodes well for a repeat

attempt with another free flap. Examples include technical errors, suboptimal postoperative management, and delay in diagnosis and salvage. Irreversible patient factors like systemic vascular disease, radiation injury, and lack of healthy recipient vessels do not preclude a further attempt but the decision to proceed with a second microsurgical reconstruction should be weighed carefully against the risks. If the risks outweigh the benefits, a nonmicrosurgical procedure may be the sensible option, although this may be just as complicated.

The need for further reconstruction is then evaluated. Factors to be considered include the extent of the failure,³³⁹ exposure of vital structures, and the effect of an open wound on subsequent therapy. An important question to address is whether the initial goal of a sophisticated reconstruction should be pursued or if a downgraded reconstruction is an acceptable compromise between achieving wound closure and the aesthetic and functional goals. Partial loss of a flap secondary to necrosis may be amenable to conservative treatment with conventional dressings, vacuum-assisted closure, or skin graft. Complete failures, such as those due to arterial insufficiency, are more catastrophic and require more aggressive treatment while venous failures deserve a more expectant management with the use of medicinal leeches or by allowing the flap to bleed out slowly to allow partial salvage. This may support a skin graft after tangential debridement.³³⁹ If the flap loss results in exposure of vital structures such as the great vessels of the neck, skull base, metal plates or bare bone, the situation may be life-threatening and mandates prompt coverage with another flap.³⁴⁰ For breast reconstruction, it is reasonable to consider primary or secondary closure if the patient can accept the cosmetic implications. In extremity reconstruction, where the threat is isolated to the extremity involved, a more expectant approach can be taken, provided metal plates or vital structures are not exposed. Less aggressive management may, however, result in higher rates of limb amputation.³⁴¹ In oncological reconstruction, the primary goal is uncomplicated wound healing in order that adjuvant therapy can proceed. In these circumstances a second flap will expedite wound healing and should be considered early. A pedicled muscle or cutaneous flap might be a reasonable alternative to a free flap, if the factors involved are irreversible or the risk of a second free flap outweighs the benefits.

Once the decision has been made to proceed, the course of action needs detailed planning. Factors to be considered include the timing of the repeat surgery, the type of reconstruction required for the resulting defect, and if there is a need for a second free flap. If a second free flap is needed, then what donor sites are available and what recipient vessels can be reliably dissected and safely used? Importantly, are the goals of reconstruction the same as they were initially?

The timing of the surgery is dependent on several factors. If the patient is unstable, then reoperation is ideally delayed. Infection-free, the flap may act as a temporizing biological dressing until the patient is fit for further surgery. The recipient site and exposure of vital structures may dictate the urgency of the surgery. If the patient is fit enough, the same second free flap should be performed at the time of adequate debridement.²⁵ In our experience of 101 failed free flaps, 34% received a second free flap³⁴⁰ and we feel a second

free flap should be attempted in any case in which failure may lead to loss of the injured limb, leave exposed major neck vessels, or cause delay in adjuvant chemo- or radiotherapy. Restoration of function should also be attempted in a previous functional muscle transfer. The success rate of second free flaps is higher in the head and neck region (94.1%) compared to that in the extremity (82.2–87.5%).^{340,342} A downgrade of reconstruction should only be considered if the patient is not in optimal condition or in the presence of overwhelming infection as this often results in poorer cosmetic and functional outcomes.

The second free flap needs to be chosen and designed carefully. It should have good vascularity and a longer pedicle as debridement may leave a larger defect, and the new recipient vessels are likely to be further from the defect. Where possible, do not reuse the previous recipient vessels as they are likely to be inflamed and friable. Interpositional vein grafts may be required but have been associated with a higher incidence of flap failure and vascular complications.^{343,344} If the same flap is available on the contralateral side, this is our flap of choice and was most commonly used.³⁴⁰ However, as it is generally accepted that a flap with an osseous component poses additional difficulties during flap elevation and inset and has been associated with a higher failure rate,¹³³ a safer option should be considered. Other indications for choosing a different type of flap (for example, choosing a myocutaneous, fasciocutaneous, or even pedicled flap with reconstruction plate over an osteocutaneous flap) include the absence (abdominal flaps) or unavailability of the contralateral side (already used or in the zone of injury) or a downgrading of the reconstructive goals due to patient fitness, altered prognosis, or the need to ensure survival.

The future of microsurgery

Has microsurgery reached a status quo yet? Or, will innovations and breakthroughs continue to endure? The authors believe that there are no definite answers to these questions; however, there could be a good chance to make a better use of microsurgery in future by proper planning and smart investment.

The following potential directions reflect some of the authors' ideas on microsurgery in the digital era.

Digital technology is always evolving and will most likely continue to evolve. Intertwining technology and microsurgery together will be a "game changer" in our practice.

Smart phone apps may revolutionize free flap monitoring³⁴⁵ and probably the whole perioperative workup by providing surgeon-friendly, fast, and, efficient tools for communication, assessment, and advice.

Google Glass or any similar products with live streaming of the surgical procedures utilizing the 4G or high-speed internet may help in telesupervision of trainees for a safer hands-on training experience.

Other technological advancements in the fields of high definition magnification and imaging can improve our understanding of the fine circulation of skin, muscles, bones, etc., resulting in custom-designed free tissue transfer; an even more refined form of supermicrosurgery.

Robots are already in use, but a specialized microsurgery robot is still lacking, which could be a product of the future; however, the wide application of robotic surgery may not witness significant change not only because of its cost but also due to limited indications.

How about the technical part itself, such as the microanastomosis, the dissection techniques, inset, etc? While the standard techniques described in the chapter will remain in use heavily, the trend towards sutureless and minimal-access surgery (in other words, a traumaless approach) will most likely continue to grow.

As for flaps and donor sites, we believe that every microsurgeon or center will have their own workhorse flaps that they rely on to achieve the reconstruction goals; however, free flaps from the lower extremity will most likely prevail over other flaps for the advantages of two-team approach and diversity of options.

Many authors have already mentioned that vascularized composite tissue allotransplantation (VCA) is the frontier to conquer, and it could be the future of microsurgery! We do not very much share that vision. This is because microsurgery is a technique utilized in the field of VCA not the opposite. Second, the main obstacle to broader application of VCA is immunosuppression not microsurgery. Although hand transplantation is not "another replantation", it relies on the same techniques used in replantation and toe-to-hand surgery. And face transplantation has its roots in facelift techniques and facial trauma and orthognathic surgery. So, the techniques are already established, and only a breakthrough in immunosuppression will lead to a revolution in VCA. Hand transplantation recorded number one in VCA may lose ground with the development of smart prosthesis. However, face transplantation may witness a flourishing future since results are encouraging and no alternative option is available, not to mention the increase in war casualties among civilians nowadays.

Finally, our words to history; microsurgery will not decline: the growing interest in learning microsurgery and the lack of comparable techniques will ensure this. Furthermore, microsurgery may become an independent specialty instead of a set of skills used by different specialties, but mainly plastic surgery. And technological refinements and breakthroughs will definitely shape the theme of future microsurgery.

Principles and applications of tissue expansion

Ivo Alexander Pestana, Louis C. Argenta, and Malcolm W. Marks

Access video lecture content for this chapter online at expertconsult.com 

SYNOPSIS

- Tissue expansion is a time-tested and simple technique to generate tissue to reconstruct defects.
- The technique stretches skin and soft tissue that have the same color and texture as the adjoining skin where expanded tissue is needed.
- In the breast, expansion is particularly useful in stretching existing anatomy to accommodate a permanent prosthesis.
- Tissue expansion principles may be combined with other reconstructive techniques to provide a safe and individualized reconstructive plan for complex bodily defects.

Introduction

The plastic nature of the human integument can be witnessed whenever the skin must allow for growth underneath it. The surgeon can take advantage of this plasticity when either medical need or aesthetic surgery would benefit from the creation of new autogenous skin. Just as development of a fetal brain will cause the overlying skull to grow, growth of the skeleton causes all normal skin and soft tissues that envelope the bone to respond and expand. Similarly, the growth of other structures inside the body will cause skin and subcutaneous tissues to expand as demonstrated by the serial growth of the abdomen with successive pregnancies. Whether the growth is caused by benign or malignant tumors under histologically normal skin or is experienced in the gravid abdomen, there is a clear response to non-genetic stimuli allowing necessary growth to accommodate underlying structures.

Since its introduction, the benefits of tissue expansion have produced a significant evolution of therapeutic techniques since donor tissue may be generated *in situ* and used for reconstruction without compromise of innervation, vascularity, or external physical appearance. One of the critical benefits of tissue expansion is the fact that there are various methods for expansion of skin, bone, and other tissues. Placement of a

prosthesis under soft tissues allows the surgeon to gradually add saline and expand subcutaneous and cutaneous tissues. External hardware is used to gradually expand fractured bone through the application of distraction forces. These techniques have been applied to the craniofacial skeleton as well as to most of the long bones of the body.^{1,2} Similarly, negative pressure wound therapy (NPWT) uses the principle of applying mechanical force to cells surrounding a wound to stimulate the induction of new tissue that will subsequently aid in closure of that wound.³

Basic science

Cellular and molecular basis for tissue expansion

The application of mechanical stress to living tissues and cells affects various cell structures and signaling pathways that are highly integrated (Fig. 25.1).¹⁵ These closely integrated cascades are theorized to explain the generation of new tissue through mechanical stimulation.¹⁶ Several *in vitro* stretching systems have been used to better understand the molecular events that occur.¹⁷ Mechanical deformation forces involve several cellular mechanisms including the cytoskeleton system, extracellular matrix, enzyme activation, secondary messengers, and ion channels.

The cytoskeleton plays a critical role in mediating the transformation of extracellular mechanical force to intracellular events. A system of microfilaments within the cytoplasm not only maintains intracellular tension and cell structure but also transduces signals to adjacent cells and initiates transduction cascades within the cell (Fig. 25.2).¹⁶ Protein kinase C plays a pivotal role in signal transduction. Mechanical strain

Historical perspective

In 1905, Codvilla applied the principles of using an external, distractive force to encourage tissue expansion in bone.⁴ Bone tissue regeneration was later documented in 1970 by Ilizarov and others, who provided roentgenographic and morphologic data from experimental distraction epiphysiolysis.² Shortly thereafter, Matev reported the expansion of bony tissue after amputation of the thumb at the metacarpophalangeal joint.⁵

In the meantime, physicians began to recognize the induction of new soft-tissue growth adjacent to the bony structures undergoing gradual lengthening. In 1957, Neumann implanted a subcutaneous balloon to induce soft-tissue growth purposefully for the reconstruction of an external ear deformity.⁶ Unfortunately, his report was considered anecdotal so progress in surgical soft-tissue expansion was delayed until the

1982 reports of using implanted silicone balloons to expand overlying soft tissue were published.

Radovan⁷ and Austad⁸ and Rose⁹ simultaneously developed the concept of implanting silicone balloons as expanders. Austad's prosthesis was a self-inflating device that used osmotic gradients driven by salt placed within the expander. His largely experimental work was critical to elucidating the physiology of tissue expansion.

Radovan's device contained a self-sealing valve through which saline was periodically injected to increase the size of the expander. His work was initially greeted with skepticism. Despite this, Grabb's enthusiastic acceptance of Radovan's technique stimulated its rapid and wide application to create new horizons in reconstructive surgery.¹⁰⁻¹⁴ Large studies subsequently confirmed the safety and efficacy of this technique.

Fig. 25.1 Effects of tissue expansion on surrounding tissue. Strain-induced responses are mediated by growth factors such as platelet-derived growth factor (PDGF) that are known to stimulate cutaneous cell proliferation. Other growth factors such as transforming growth factor- β (TGF- β) may stimulate extracellular matrix production. Membrane-bound molecules including protein kinase play a key role in regulating intracellular signaling cascades. EGF, epidermal growth factor. (Adapted from Takei T, Mills I, Arai K, et al. *Molecular bases for tissue expansion: clinical implications for surgeon*. *Plast Reconstr Surg*. 1998;102:247–258.)

on cell walls activates inositol phosphatase, phospholipase A₂, phospholipase D, and other messengers. Activation of these components leads to activation of protein kinase C, which suggests that intracellular signals can be transmitted to the nucleus. Protein kinase C activation has been noted in human cells subjected to strain *in vitro*.¹⁶

The mechanical effects of negative pressure wound therapy (NPWT) on wounded tissues and their subsequent cellular and molecular effects are actively being studied. At a cellular level, NPWT alters wound bed gene

expression with resultant changes in cytokine/chemokine/growth factor expression and matrix metalloproteinase expression. In human and animal models, increases in anti-inflammatory cytokines (IL-10) and pro-angiogenic growth factors (VEGF, FGF, PDGF) have been demonstrated with the use of NPWT. The above, in conjunction with reduction in MMP expression, indicates that NPWT may promote healing by modulation of cytokines to an anti-inflammatory profile and alteration in mechanoreceptor and chemoreceptor mediated signaling to culminate in angiogenesis and

Fig. 25.2 Schematic of possible signal transduction pathways induced by mechanical strain. Transduction pathways are activated by numerous strain-induced signals transmitted through various membrane receptor or membrane ion channels. Terminal enzymes that are activated by these intracellular cascades transduce these signals into the nucleus. cAMP, cyclic adenosine monophosphate; DAG, diacylglycerol; IP₃, inositol 1,4,5-triphosphate; JNK, c-Jun amino-terminal kinase; MEKK/MEK/MAPK, mitogen-activated kinases; PGE₂, prostaglandin E₂; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C.

extracellular matrix remodeling for the deposition of granulation tissue.¹⁸

Biology of tissue expansion

Extensive information is available regarding the biology of tissue expansion. After the completion of animal experiments,^{9,19} studies on human tissue examined the process of tissue expansion that occurs both during the period of expansion and postoperatively.²⁰ Studies of the effects of tissue expansion on nerve, muscle, and bone have also been published.

Skin

Statistical analysis of multiple sites over the implant and its periphery has revealed a significant increase in epidermal thickness during the process of expansion and this thickening occurs soon after expander placement. This is also seen in sham controls and may represent, in part, postoperative edema. Within 4–6 weeks, epidermal thickness generally returns to initial levels, but some increase in thickness persists for many months.

The increased area of skin over the expander includes not only normal skin recruited from adjacent areas but also new skin generated by increased cellular mitosis.²¹ Hair follicles are not reproduced in humans, so individual follicles are distracted during expansion. Distraction between follicles is less noticeable in blondes than in dark-haired individuals. Melanocytic activity is increased during expansion but returns to normal levels within several months after completion of the reconstruction. Although hair follicles and accessory skin structures are compressed by tissue expansion devices, they show no evidence of degeneration.

During expansion, the dermis decreases rapidly in thickness over the entire implant. Thinning is most pronounced in the first several weeks after implant placement and persists for the entire period of expansion. Dermal thinning persists at least 36 weeks after expansion is completed.²²

Capsule

A dense fibrous capsule that becomes less cellular over time develops around the implant. Progressive collagen deposition occurs over 3 months with the development of well-organized collagen bundles. Molecular studies have demonstrated up-regulation of the wingless (Wnt) signaling pathway in the pathogenesis of inflammation and capsule fibroproliferation which may contribute to capsular contracture seen after radiation therapy in breast cancer patients. Such increases have not been demonstrated in non-irradiated tissue. This is further supported by the growing body of evidence demonstrating decreases in inflammatory markers and limited capsule formation associated with the use of acellular dermal matrices (ADMs).²³ Although no evidence of dysplastic changes or loss of normal cell maturation has been observed, dystrophic capsular calcification may occur with repeated trauma to the prosthesis or with hematoma resolution. After prosthetic removal, the capsule resolves and little clinical or histologic evidence of it remains over time. Histological examination of capsular tissue demonstrates an extensive vascular plexus within collagen such that capsule itself can be harvested as a local flap because of this induced vascularity.

Muscle

Muscle atrophies significantly during the process of expansion, whether the prosthesis is placed above or below a specific muscle. The effects on human muscle after expansion during breast reconstruction have shown occasional histologic ulceration. Focal muscle fiber degeneration with glycogen deposition and mild interstitial fibrosis has been identified. In addition, some muscle fibers show disorganization of the myofibrils in the sarcomeres.²⁴ Animal studies on the morphologic changes in skeletal muscle suggest that the expansion of skeletal muscle is not a stretching process but is rather a growth process of the muscle cell accompanied by an increase in the number of sarcomeres per fiber. Expanded skeletal muscle returns to normal muscle architecture, vasculature, and function after the prosthesis is removed.²⁵ Moreover, muscle mass returns to normal levels after removal of the device in humans.

Bone

The effect of expansion on underlying cranial bone has been studied in animal models. Decreases in both cranial bone thickness and volume are evident beneath the expander where bone resorption occurs. In contrast, there is an increase in bony thickness predominantly at the expander periphery where a periosteal inflammatory reaction is seen. Bone density is unaffected.

Expansion over the cranium in children under one year of age should be done judiciously. Depression of cranial bone during expansion may occur before one year of age but usually corrects itself once the expander is removed. In the face of expansion, cranial bone appears to be measurably more affected in thickness when compared to that of long bone. Long bone remodeling begins within 5 days after removal of the expander and the long bone is completely normal within 2 months. Remodeling in cranial bone is complete in 2–3 months.

Vascularity of expanded tissue

The robust vascularity of expanded tissue was clinically evident long before laboratory work measured it (Fig. 25.3). It has been clinically and histologically demonstrated that a large number of new vessels are formed adjacent to the capsule.²⁶

The content of collagen fibers in existing vessels initially decreases after expansion while elastic fibers in existing blood vessels initially increase in response to mechanical stress. Angiogenesis occurs in response to induced ischemia of the expanded tissues. The number of cells expressing vascular endothelial growth factor (VEGF) is significantly higher in expanded tissue than in non-expanded, similar tissue.²⁷ Expanded fascial flaps show a measurable increase in vascularity between the fascia and subcutaneous tissue. Increased perfusion to the distal and peripheral areas of the flap also increases the robustness of the flap and the possibility of harvesting a larger flap.²⁶ Similar studies on prefabricated, expanded, pedicled flaps have shown increased vascularity within the pedicle, as well as in the adjacent random areas.²⁸

The increase in vascularity affords the expanded tissue important functional benefits. Animal studies have shown that flaps elevated in expanded tissue have significantly

Fig. 25.3 Transillumination of expanded human skin demonstrating an intense increase in arterioles and venules as well as a dense, interconnecting capillary bed. The proliferation of capillary bed renders the overlying skin erythematous.

greater survival areas than acutely raised and delayed flaps (Fig. 25.4).²⁹ Similar studies employing labeled microspheres have demonstrated an increase in flap survival, as well as increased blood flow in the expanded tissue.

Diagnosis and patient presentation

The principles and technique of tissue expansion can be applied in the management of myriad diagnoses with their associated reconstructive dilemmas, therefore patient presentation is variable. Examples of diagnoses where tissue expansion may be utilized include, but are not limited to, traumatic injuries and burns, male-pattern baldness and other forms of alopecia, benign and malignant tumor extirpation defects, breast deformities, and congenital or acquired craniofacial deformities.

Patient and implant selection

Tissue expansion is a protracted procedure that may involve temporary, but very obvious, cosmetic deformity. In general, emotionally stable patients of all ages tolerate tissue expansion well. Noncompliant or mentally impaired patients are poor candidates for this technique. Although not an absolute contraindication, tissue expansion in smokers is associated with a higher risk of complications.³⁰

Tissue expansion is generally best performed as a secondary reconstructive procedure rather than in the acute trauma

Fig. 25.4 Barium-injected radiograph of vessels in a random-pattern skin flap in a pig (A) and an expanded flap in the same animal model (B). A dramatic increase in the vascularity of the expanded flap is evident. (From Cherry GW, Austad E, Pasyk K, et al. *Increased survival and vascularity of random-pattern skin flaps elevated in controlled, expanded skin*. *Plast Reconstr Surg*. 1983;72:680–687.)

period. Expansion can be performed adjacent to an area of an open wound before definitive closure, but such a procedure carries the risks of infection, implant extrusion, and less-than-optimal results. Tissue expansion is best suited to those patients who require definitive, optimal coverage when time is not of the essence.

Implant types

Radovan's initial expander consisted of a silicone prosthesis with two valves, each connected to the main reservoir by silicone tubing.⁷ One valve was used to inject fluid while the other was used to withdraw fluid. Technologic improvements have allowed for the availability of a wide variety of off-the-shelf and custom implants of any shape. These advances have also decreased the incidence of mechanical failure associated with earlier generation implants.

Advances in implant technology include the production of a single valve that allows for fluid injection or removal as well as integrated valves within the expander reservoir. Prostheses that expand differentially into a specific shape, rather than the usual round or rectangular configuration, are also available. Differential expanders have found the most use in reconstruction of the breast, where ptosis and projection of the inferior-most portions of the breast are desired. Low-profile implants that accordion on themselves have been designed to eliminate fold-flaw erosion early in the expansion process. Further modifications of tissue expanders have been made to incorporate surface textures with the theoretical advantages of better tissue adhesion producing decreased rates of implant malposition and capsular contracture.

Expanders with distal ports

Remote filling ports have the advantage of minimizing the risk of implant puncture during inflation. The distal, self-sealing injection port and inflation reservoir are connected to the prosthesis by a length of tubing. This allows the injection port to be placed away from the expander pocket and is advantageous when the overlying skin and soft tissues are thin or when the pocket is too tight to hold an expander with an integrated valve safely.

It is also possible to move the inflation port of a distant reservoir to the exterior of the body. External location facilitates inflation, particularly when the expansion is accomplished by ancillary help or family. Concerns about colonization risk can affect both selection of an implant and management of complications.

Expanders with integrated ports

The inflation reservoir may be incorporated directly into the prosthesis. Such devices have the advantage of avoiding the remote port and its associated mechanical problems. However, the risk of inadvertent perforation of the prosthesis during inflation is higher with integrated valves because the valve and integrated prosthesis can be difficult to palpate. Magnetic and ultrasonic devices can be useful when the valve is difficult to locate and metal-finding devices have been designed. Expander prostheses with integrated valves are particularly popular for breast reconstruction where adequate soft tissue and implant pocket can accommodate the added projection of the injection port.

Self-inflating expanders

Self-inflating expanders have become available largely outside of the United States.³¹ These implants contain osmotic active hydrogel (vinyl pyrrolidone) that causes migration of extracellular water through the silicone membrane of the device resulting in progressive enlargement of the expander. Another type of self-inflating expander employs carbon dioxide for filling. Through an internal carbon dioxide reservoir and valve operated by a remote radio-control, small fixed amounts of the gas are released into the expander resulting in progressive enlargement.

The first such expander was devised by Drs. Austad and Rose. The first generation of osmotic tissue expanders were designed without an envelope allowing rapid swelling within the first few days after implantation resulting in soft tissue ischemia in some cases.⁹ Modifications of these implants to include a silicone membrane which encloses the osmotic tissue expander significantly decreased expansion speed and improved size consistency after complete expansion.³² These implants are currently not approved by the Food and Drug Administration and are not available in the US.

Gas-filled self-inflating expander use in humans was initially reported in 2011 by Dr. Anthony Connell.³³ Seven women with 10 carbon dioxide expanders underwent successful expansion. Subsequent to this proof-of-concept series, Dr. Connell has demonstrated 100% expansion success rate with only minor adverse events and high patient satisfaction.³⁴

Self-expanding devices have the theoretical benefit of continuous or patient-controlled inflation of the prosthesis. Further benefits may include reducing the number of office visits, decreased pain, no need for patient needle sticks, and more rapid expansion. Such prostheses have the downside of potential continued expansion even if overlying tissue becomes compromised.

Incision planning and implant selection

The key to successful expansion is meticulous planning before any incision is made. The proposed type of flap (advancement, rotation, or interposition) that is to be expanded should be carefully planned. In general: the simpler the flap, the less the potential for complication. Ideally, planning is done so that: (1) incisions are incorporated into tissue that will become one margin of the flap; (2) aesthetic units are reconstructed; (3) scars are in minimally conspicuous locations; and (4) tension on suture lines is reduced. The length and position of resultant scars play a major role in determining the overall cosmetic postoperative result. Careful planning allows the prosthesis to be placed through an incision that will both minimize the risk of compromise during flap development and optimize cosmetic reconstruction.

Incisions should be planned to minimize tension on the suture line and risk of extrusion. Tension from the initial inflation on the suture line will be greater when incisions are parallel to the direction of expansion than when they are perpendicular to it. Undermining of the prosthesis should be sufficient enough that the prosthesis can be easily accommodated and the wound can be closed in multiple layers. The inflation valve and tubing should be maintained at a site away from the incision.

Choice of an implant with an external distal port may affect surgical planning. Cultures of implants with external valves

revealed that 82% of these prostheses had colonized the expander capsule and had some infection present which constitutes an infection risk that is slightly higher than that of totally buried prostheses.³⁵ Although patients tolerate this colonization well and experience few complications, external ports are contraindicated when a permanent prosthesis or bone grafts are to be used after expansion is complete.

The size of the implant selected should closely relate to the size and shape of the donor surface. An implant equal to or slightly smaller than the donor area is selected. Because there is minimal risk in hyper-inflating the prosthesis to several times the manufacturer's designated volume, less importance is placed on the implant's specific volume than on its overall base size. On occasion, a custom-fabricated implant may be necessary.

In general, the use of multiple small expanders is better than the use of one large expander. Inflation of multiple prostheses proceeds more rapidly and complications are fewer. Multiple expanders also allow the surgeon to vary the plan for reconstruction after expansion has been achieved.

Because of the variety of functional, medical, and surgical considerations, the choice between an integrated valve and a distal inflation port should be considered on a case-by-case basis, without neglecting plans for infection control and the possible need for nonmedical personnel to inflate the implant.

Implant and distal port positioning

If a remote or distal filling port and reservoir is chosen, it must be placed superficially in subcutaneous tissue, where even an extremely small port is easily palpable under stable skin. To minimize discomfort, it is occasionally possible to position a filling port in an area that is relatively less sensitive. The port should be placed in a location that will not be subjected to pressure when the patient is lying in a position that could put direct pressure immediately over the fill port. Bony prominences are avoided if possible.

Care must be taken to avoid kinking of the tubing so that the injected saline will flow readily to the prosthesis. The prosthesis tubing should avoid the incision through which the implant is placed and should not traverse joints. If placement of an external valve is chosen, the connecting tubing should be tunneled a significant distance from the prosthesis.

Tissue expanders are usually placed beneath the skin and subcutaneous tissue above fascia. When the subcutaneous tissue is thin or the risk of extrusion is significant, prostheses may be placed under muscle.

Treatment and surgical technique

Burns

The use of tissue expansion in the reconstruction of burns, particularly involving the scalp and face, has revolutionized the treatment of burn patients. Because there is almost always inadequate tissue after burns, reconstruction should be carried out after all burns have thoroughly healed and scars have matured. Planning is particularly important in these cases so that a minimum number of suture lines are produced and that these suture lines do not cross aesthetic units. Significant late distortion and contracture may result in excessive scars placed in burned tissue, particularly in the facial area.

Skin that has suffered a partial-thickness burn or that has been scarred by adjacent burns is attenuated and is more amenable to expansion.³⁶ Incisions can be placed in previous scars, but the scar should be mature and relatively thick so that extrusion does not occur. Using an access incision within normal tissue that is peripheral to the burned area further minimizes the risk of extrusion. The principle of using multiple, smaller-volume prostheses is especially appropriate in the burn patient. Perioperative antibiotics and meticulous preparation are always used since the incidence of infection is higher in burn patients.

Tissue expansion in children

Skin and soft tissue are always thinner in children than in adults. These tissues are probably better vascularized but less resistant to trauma. Tissue expansion has a higher complication rate in children than in adults. Rather than using excessively large prostheses or expanding tissue aggressively, accomplishing serial repeated expansions may be helpful in children. This is done with the understanding that major complication risk – particularly extrusion – is more common at the second, third, and fourth serial expansion.³⁷ This is particularly true in the head and neck (with the exception of the scalp). Expansion of the facial areas and neck can be particularly difficult.

After age five, most children are able to adequately cooperate therefore complication rates decrease. In many children, an external reservoir is used to minimize the amount of emotional trauma caused by injections. Application of EMLA to the skin over the buried injection port is also helpful in minimizing discomfort. Small volume inflation at frequent intervals is especially useful in children because the amount of pain generated is considerably less.

As in all cases, planning should be meticulous so that the flaps generated will result as much as possible in reconstruction of anatomic units. With growth, contracture may occur, particularly about the mouth and around the orbits, and revision will be required.

Expansion of myocutaneous, fascial, and free flaps

Myocutaneous flaps are the standard of care for the treatment of large defects, particularly when bone and vital structures are involved. The territories of standard flaps are well described. These territories can be considerably enlarged by placing an expander beneath the standard myocutaneous flap, and an extremely large flap can be developed over a short period. Expansion increases the vascularity of the flap and allows a large, adjacent random area to be carried with the original flap.³⁸ The vascular pedicle of such flaps remains intact and may in fact be elongated, thus allowing flaps to be transferred farther.

Myocutaneous flaps such as the latissimus dorsi and pectoralis major can be expanded to almost double their surface area, allowing coverage of almost any defect of the abdomen or thorax.³⁹ Expanders of up to 1000 mL can be placed beneath such flaps and rapidly expanded. For example, bilateral latissimus dorsi myocutaneous flaps can be expanded and moved to the midline to cover large meningoceles or the vertebral column. In these cases, one edge of the myocutaneous flap is selected for implant placement, and care is taken not to injure

the vascular pedicle. The expanded myocutaneous flap generated can then be transferred as either a pedicled flap or a free flap. Such expanded flaps not only provide coverage of other donor defects but also preserve the function of the muscle.

Fasciocutaneous flaps can be expanded either before or after transposition. When flaps are expanded before transfer, it is best to keep the prosthesis as far away from the pedicle as possible, thus preferentially expanding the random area of the flap. Within 6 months of transfer of these flaps, the random blood supply is usually sufficiently established to allow placement of the expander anywhere under the flap.⁴⁰

Expanded full-thickness skin grafts

Because a donor defect is usually created by harvesting full-thickness grafts, their use is infrequent. The placement of a large tissue expander beneath the donor site can result in a large full-thickness graft that is particularly useful in resurfacing large areas of the face or the entire hand or foot. Expanded full-thickness grafts are extremely resilient and have been shown to grow in children over time. The rate of contracture is significantly less than that of split-thickness grafts.

The best color matches are generated when the full-thickness graft is expanded and harvested as close as possible to the recipient site. The periorbital area and the area around the mouth are particularly well suited to reconstruction with expanded full-thickness grafts harvested from the supraclavicular area. Expanded full-thickness grafts are very helpful in reconstructing defects of the forehead that encompass more than 70% of its surface area. A single full-thickness graft can be harvested from the supraclavicular area or from under the breast fold. Care must be taken that hair-bearing tissue is not transferred to an area that normally has no hair. Expanders with a surface area equal to that of the donor site are placed through peripheral incisions. The prosthesis is then inflated to an adequate volume. After sufficient donor tissue is generated, a template is made of the recipient site and transferred to the expanded donor area. The full-thickness graft is harvested so that it is approximately 10–15% larger than the recipient area, allowing for some contracture. The prosthesis is then removed, leaving the capsule intact, and the donor site closed primarily. Closing of the donor site should be done so that the resulting scar is as inconspicuous as possible. In the recipient site, expanded full-thickness skin grafts require more immobilization than do split-thickness skin grafts. A bolster dressing or, ideally, a VAC sponge dressing is required. The graft is sutured in place, a VAC sponge placed over the graft, and 125 mmHg of negative pressure is maintained for 4 days. Successful take of such grafts placed with this technique is extremely high.

Reconstruction in the head and neck

The head and neck area contains many specialized tissues that must be matched appropriately to achieve optimal aesthetic reconstruction. Aesthetic reconstruction is maximized by mobilization of adjacent local tissues rather than by transfer of distant tissues with poor match of color, texture, or hair-bearing capability. Tissue expansion therefore allows optimal aesthetic reconstruction by use of a similar adjacent tissue area to reconstruct a defect without creation of a donor site.^{11,41}

The skin of the face can be subdivided into five tissue-specific areas:

1. The scalp is unique in that it contains specific hair-bearing qualities that cannot be mimicked by any other tissue of the human body.
2. The forehead is a continuation of the scalp, but it is distinguished from the scalp by its thick skin, large number of sebaceous glands, and lack of hair.
3. The nose is embryologically related to the forehead, so it closely mimics the forehead in color, texture, and sebaceous gland content.
4. The lateral cheek areas, neck, and upper lip have fewer sebaceous glands; the skin is thinner, and the hair-bearing pattern is significantly different in quality and quantity from that on the remainder of the body.
5. The skin of the periorbital areas is extremely thin and pliable, containing a minimal number of sebaceous glands.

There is a limited amount of tissue on the human face, so procedures must be planned carefully and reconstruction accomplished correctly at the first attempt. Correct planning should take into consideration the area and shape of the defect, quality of the remaining tissue of the aesthetic unit, pre-existing scars, and reconstructive needs of other areas of the head and neck. Because of the risk of complications, it is prudent to plan alternative reconstructive strategies before any prostheses are placed. If there is a chronic infection, the presence of fistulas, or the need to reconstruct facial mass/volume, other reconstructive alternatives may achieve a better final result.

Scalp

Tissue expansion is the ideal procedure for the reconstruction of scalp defects (Fig. 25.5).⁴² Expansion of the scalp is well tolerated and is the only procedure that allows development of normal hair-bearing tissue to cover areas of alopecia. The amount of scar and deformity generated is considerably less than with previous procedures such as serial reduction and complex multi-flap procedures. While some animal studies have demonstrated an increase in hair follicles during tissue expansion, our clinical experience suggests that humans do not form a significant number of new follicles. Rather, existing follicles are redistributed to a larger surface area. Because of the finite number of follicles, attempts should be made to redistribute them as homogeneously as possible. To accomplish this, large or multiple expanders, expanding large areas of the remaining scalp, produce the best results. Hair follicles can be separated by a factor of 2 without producing noticeable thinning. The darker the hair, the more visible the thinning is. Individuals who have large defects and require extreme expansion may achieve better results by lightening the hair color with dyes.

Although there is considerable overlap in the vascular territories of the scalp, the incorporation of one or more major vessels of the scalp optimizes reconstruction. Flaps should be well vascularized to ensure maximum growth of hair. Planning is therefore of importance, as is consideration of scar and previous areas of trauma. Advancement or rotation flaps achieve the best results, particularly when the anterior hairline is reconstructed. Simultaneous expansion and mobilization of the forehead may also help achieve a normal hairline.

Previous scars and incisions can be used for placement of the prosthesis. Once the galea is encountered, dissection can proceed widely with a blunt dissector. It is not unusual to

Fig. 25.5 (A) Young woman with avulsion injury to the right scalp, which had been covered with a transposition flap from the left scalp that resulted in a scalp and forehead skin graft. Two expanders were placed, one on either side, encompassing as much of the hair and forehead as possible. (B) Expanders removed and advancement flaps ready for repositioning. (C) Patient shown postoperatively with a normal hairline, normal brow, and normal hair-bearing scalp.

mobilize most of the remaining scalp so that the prosthesis is well accommodated. Individual pockets are not necessary for multiple expanders, but care should be taken to fix the inflation reservoirs so that they do not migrate into a common pocket. Prostheses with incorporated inflation reservoirs can also be used, but patients often find them bulky and uncomfortable. Inflation reservoirs can be placed at the vertex of the scalp or in the forehead but care should be taken not to place them where pressure is applied during sleep.

Expansion of the scalp is initially uncomfortable. It is better to use frequent small saline injections than to use infrequent large injections. After several weeks, the scalp loosens, and large amounts of saline can be infused without difficulty. Most scalp expansions can be accomplished in 6–8 weeks, particularly when multiple expanders are used.⁴³

Once adequate expansion has been achieved, the prostheses are removed through the incisions through which they were originally placed or at the margin of the flap to be moved. Flaps should be designed for advancement, transposition, or rotation. Every attempt should be made to minimize transection of the major vessels of the scalp as this will allow faster healing and better regeneration of hair follicles. Removal or cutting of capsule and galea should be avoided in order to preserve blood supply. Large areas of the scalp are mobilized and positioned by temporary staples. Dog-ear deformities created with flap inset are left in place because they subside over time. The wounds are then closed.

It may be impossible to gain an adequate amount of tissue with one expansion when large areas of the scalp must be resurfaced, in which case serial expansion is used (Fig. 25.6). After the initial expansion, flaps are advanced as far as possible. Lesions or areas of alopecia are excised only after the flap has been advanced. The expander is then left in place under the flap and, after several months, the scalp is re-expanded. Adults tolerate three or four sequential expansions without difficulty. The skin of infants and children may thin excessively after two expansions and an interim period of 8–12 months is optimal for a later expansion.

In growing children, scars frequently widen over time. These require revision when they become a cosmetic problem, optimally after 16–18 years of age. Scalp that has been vigorously expanded may lose some hair follicles, but these usually regrow hair. Twelve months should pass before any areas of alopecia are considered permanent.

Some erosion and depression of the skull may be seen in children radiographically and, occasionally, clinically. Expansion should best be delayed in children until they are approximately 1 year of age. By this time, the skull is solid enough that significant erosion is not a cause for concern. Long-term studies have demonstrated no detrimental growth of the skull in children who have undergone scalp expansion in infancy (Fig. 25.7).

Male-pattern baldness

Tissue expansion can be used to develop hair-bearing flaps that will replace skin that is affected by male-pattern baldness.^{44,45} Expansion allows the homogeneous distribution of the remaining hair follicles and reduces the tension that can be caused by excision of scalp.

In patients with vertex baldness, the remaining temporal and occipital scalp can be expanded for 2 months. Expanders

Fig. 25.6 (A) Child born with a giant hairy nevus occupying one-third of the scalp. (B) The remaining normal scalp was expanded, allowing removal of more than half of the lesion. (C) The original expander was left in place and 4 months later re-expanded, generating tissue that allowed removal of the remaining lesion. (D) The patient is shown 1 year after expansion. (E) The patient 10 years after expansion with stable hairline and normal hair distribution. (F) Patient shown at age 18. No revisions have been required.

are placed through incisions that would normally be used for scalp reduction. Cosmetic deformity during this process may be significant after the first several weeks. At the second procedure, the scalp is advanced as far as possible and the area of alopecia removed.

Patients who are unable to accept the deformity that occurs with single large expansions can be serially expanded and undergo serial scalp reduction. In these patients, the prosthesis is inflated until deformities become visible. The expanders are deflated and the hair-bearing flaps advanced as far cephalad as possible. The prostheses are left in place, and a second or third expansion is carried out until the entire bald area is removed.

Expansion can also be used to significantly increase the size of standard transposition flaps used in the management of male-pattern baldness. Anterior baldness that affects the hairline can be modified into a new, natural-looking hairline with Juri transposition flaps. However, these flaps are limited in size and may require multiple delays to ensure adequate hair viability.⁴⁶ Expanders placed beneath the temporoparietal area can dramatically increase the size of Juri flaps and increase their safety. Bilateral flaps, one transposed behind the other, will cover the entire forehead and a significant portion

of the scalp behind it. The bilateral advancement-transposition flap is especially efficacious in transposing a large amount of hair to the forehead.⁴⁷

Forehead

The forehead is anatomically and histologically identical to the scalp except for its different numbers of sebaceous glands and hair-bearing follicles. Reduction or increase of the surface area of the forehead by 20–25% is not usually readily apparent after appropriate hair styling. By expanding the scalp in conjunction with expanding the forehead, better symmetric brow positioning is achieved while maintaining the normal hairline.

In individuals with very high hairlines, the scalp can be expanded posteriorly and brought forward to the junction of the forehead and scalp. Generally, a lateral movement of scalp tissue is less visible postoperatively. When defects involve tissue lateral to the orbit, expansion of the cheek area with cephalad movement of the exposed tissue may be helpful. The temporal hairline and the lateral hairline that lies anterior to the ear can be reconstructed with an advancement or transposition of a scalp flap.

Fig. 25.7 (A) An infant born with severe aplasia cutis congenita involving the scalp, skull, and derma that left exposed brain. (B) The brain was covered immediately after birth with two, large, scalp-forehead advancement flaps. Absence of the cranium prevented the patient from attending school. (C) At age 4 years, the flaps were separated from the underlying brain; a reinforced polyethylene sheet was secured to the cranial defect, an expander was placed over the sheet, and the scalp was expanded for 3 months. (D) The cranium was reconstructed with multiple split-rib grafts within the expanded capsule. (E) One year later, the scalp was re-expanded to more than 1000 mL over the reconstructed cranium. The skin graft was excised and the scalp and forehead flaps were repositioned appropriately. The reconstructed skull suffered no ill effect during the re-expansion. (F) Patient shown 1 year after reconstruction. (G) The patient at age 36 with an intact skull, normal scalp, and minor alopecia. (H) Posterior scalp showing thinning of hair-bearing tissue, but a resilient, pliable scalp over an intact cranium. (From Argenta LC, Dingman RO. Total reconstruction of aplasia cutis congenita involving scalp, skull, and dura. *Plast Reconstr Surg.* 1986;77:650–653.)

Prostheses are usually placed in the forehead through an incision in the scalp. The prostheses are placed beneath the frontalis muscle because this plane is safe and a well-vascularized flap can be developed. Multiple expanders are usually needed both to generate adequate tissue to be mobilized and simultaneously to allow the brows to remain in an appropriate symmetric position. Expansion is at first difficult and uncomfortable, but as in the scalp, the expansion proceeds rapidly after several weeks. Flaps may be developed in any direction but are usually simple advancements. The adjacent scalp should be mobilized at the same time so that a normal hairline can be reconstructed.

Expansion of the forehead is useful in many craniofacial anomalies with low hairlines. Expansion of the remaining forehead is accomplished and moved in a cephalad direction. The intervening hair-bearing scalp is excised. Fixation of the

expanded forehead to the underlying skull with small screws reduces the amount of retraction.

If the entire forehead must be reconstructed, the optimal choice is the use of an expanded full-thickness graft from the neck. These grafts must be secured in place with negative-pressure devices for at least 4 days.

Lateral face and neck

The type of skin on the lateral facial areas and neck is essentially the same. This skin has hair-bearing potential and is relatively thin, but contains numerous oil and sebaceous glands. It is much thinner than skin on the forehead and nose.

A large Mustardé expanded rotation flap can be developed on the neck for use in facial reconstruction. In children, there is a higher risk of extrusion problems in the expansion of this

Fig. 25.8 (A) An infant with a giant hairy nevus of the face. (B) The neck and lateral face were expanded by placing a prosthesis through an incision in the nevus. An expanded Mustardé cheek rotation flap was rotated as an aesthetic unit over the lateral face. (C) The patient at 5 years of age. (D) The patient at 18 years of age with minimal scars that are easily amenable to makeup. (E) Lateral view demonstrating no ectropion and an aesthetic reconstruction.

Fig. 25.9 (A) Young man who sustained extensive burns over the face, but in whom the neck was largely spared. (B) Bilateral large expanders were placed in the neck and the entire neck and upper chest were expanded dramatically. (C) The area of burned skin over the lower face was excised and the neck flap advanced superiorly. The capsule was secured firmly to the muscle on the lateral commissures to minimize later distortion of the mouth. (D) The patient 2 years later. The upper lip has been reconstructed as an aesthetic unit from hair-bearing, temporoparietal flaps.

area of the face (Fig. 25.8). In adults, such reconstruction can be accomplished with relative ease. The flap is based inferiorly and medially.

The prosthesis is inserted through a preauricular facelift-type incision. The platysma should not be incorporated because doing so exposes the marginal mandibular nerve to trauma and restricts flap advancement. Distal reservoirs are usually placed in the neck or behind the ear. The prosthesis is then inflated as tolerated by the patient. Despite placement of the prosthesis over the carotid artery and jugular vein, few complications have been encountered. Once an adequate amount of tissue has been generated, the Mustardé flap is elevated. This is done through a preauricular incision that is carried in front of the hair-bearing scalp and then on to the lateral orbital area above the lateral canthus. The flap is then rotated medially and superiorly to cover the areas of the cheek that require resurfacing. In general, it is best to rotate this flap and secure it in place with temporary staples before the recipient area is excised. It is best not to carry the medial scar in this flap beyond the lateral commissure because scars below that feature tend to distort the mouth. The flap is suspended both medially and laterally at a level above the canthus which minimizes the development of later ectropion. If coverage is required for the periorbital area, this is done as a separate aesthetic unit graft, usually a full-thickness graft from the supraclavicular area.

The lower half of the face and the neck are aesthetically the same unit. Hair distribution, sebaceous gland density, and skin thickness are similar. Defects of the lower face and neck can be interchangeably reconstructed by expanding either the lower face or the neck. Most frequently, the neck is expanded and the flap advanced into the lower face. If necessary, bone grafts that are placed beneath the expanded flap can reconstruct the mandible and maxilla. The prosthesis should be placed in the neck superficial to the platysma muscle. Once an adequate amount of tissue is generated, the flaps can be brought superiorly to cover the lower edge of the face, medially to cover the central portion of the neck, or laterally in the neck as needed (Fig. 25.9). In cases where flaps are brought from the neck into the face, it is important to secure the flap with permanent sutures to the deep muscles at the commissures of the mouth. If this is not accomplished, oral incontinence may develop later. Form-fitting neck collars may be necessary to secure the expanded flap in place over the neck after a portion of it has been brought on to the face.

Nose

Reconstruction of major defects of the nose, including total nasal reconstruction, may be facilitated by pre-expanding the forehead skin. Before the use of tissue expansion, having both

inadequate amounts of tissue and difficulty closing the forehead could be anticipated. However, now, when total nose reconstruction is performed, expansion of the entire forehead with a 400–600-mL prosthesis generates an adequate number of large, well-vascularized flaps to accomplish both total nose reconstruction and closure of the donor site. Because the color and texture of the forehead are ideally suited to reconstruction of the nose, this procedure makes reconstruction of any nasal defect possible.

Any of the standard forehead flaps can be employed in conjunction with expansion. If reconstruction of the nasal lining is also necessary, expansion of a forehead or Converse scalping flap develops enough tissue to allow folding of the expanded tissue on itself.

The supraorbital and supratrochlear vessels are located by Doppler examination, and the nasal flap is based on the location of either of these axial vessels. Prostheses are best placed beneath the frontalis muscle through an incision above the

Fig. 25.10 (A) This woman had her nose resected for a mucosal melanoma. Three years later, reconstruction was begun by placement of a 450-mL expander in the forehead. (B) At the second procedure, the infrastructure of the nose was made with a cantilever bone graft and bilateral, conchal cartilage grafts. (C) The forehead flap was turned down in the subperiosteal plane to the level of the medial canthus. (D) The distal third of the flap was markedly thin so that the skin could be turned on itself to recreate the nasal lining. (E, F) The patient 11 years after reconstruction with a functional breathing nose. No further modifications have been required in the succeeding 24 years.

Fig. 25.11 (A) A complex midface giant hairy nevus in a newborn. Reconstruction was undertaken in multiple stages at 2.5 years of age. (B) Bilateral expanders were placed in the neck area to reconstruct the lateral face and a third expander was placed in the lateral thoracic wall to generate an expanded, full-thickness skin graft. (C) Bilateral Mustardé cheek flaps were advanced as aesthetic units. Note that the nevus outside the anatomical aesthetic unit was left in place to be resected later. (D, E) The forehead was excised and a full-thickness skin graft was harvested from the expanded right thoracic wall.

hairline. At the second procedure, the expander is removed and the flap, including the capsule, is rotated inferiorly. Approximately 2 cm above the supraorbital rim, the posterior capsule is incised, and development of the flap is continued in a subperiosteal plane. This allows further mobilization of the flap into the orbit and dissection may continue almost down to the canthus.

Having sufficient bony and cartilaginous supporting structures of the nose is critical to avoiding contraction of the

expanded tissue. Early experience in use of expanded forehead tissue was unsuccessful because the underlying bony and cartilaginous structure was not adequate. A cranial bone or rib graft is taken to reconstruct the dorsum of the nose. This is either secured to the remaining nasal bone or attached by a plate to the skull. The nasal cartilage is reconstructed bilaterally with cartilage from the conchal bowl. Thinly carved rib cartilage is also useful if the ear cartilage is inadequate. Nasal stents are used for 3–4 months to maintain a patent airway

Fig. 25.11, cont'd (F) The expander in the lateral thoracic area was left in place and re-expanded. In a later procedure, the remaining areas of nevus in the nasolabial folds on each side were excised. The entire periocular and nasal area was then excised and grafted with full-thickness, expanded graft. **(G, H)** The patient 5 years after reconstruction with a stable result. **(I–K)** The patient at 21 years of age. Note that the face has grown normally and symmetrically and that facial nerve function has been maintained. The patient is able to hide remaining scars with minimal makeup.

while the flap matures. The forehead flap is divided and inset approximately 2 weeks after rotation. Some swelling and contracture of tissue may occur, but major touch-ups are infrequently needed (Fig. 25.10).

Ear

Most cases of microtia and traumatic ear deformities can be reconstructed without expansion. Expansion is helpful when skin and soft tissue are insufficient for reconstruction. As with all ear reconstructions, a child should be approximately 7 years of age before reconstruction is begun. A custom or rectangular expander is placed beneath the remaining non-hair bearing tissue that is adjacent to the ear remnant. The

prosthesis is then expanded and left in place for approximately 3 months. This allows both significant thinning of the overlying skin and tissue maturity that will together result in minimal secondary distortion due to contracture.⁴⁸

The expander is best placed through an incision in the postauricular hair-bearing tissue, preserving the temporoparietal fascia for possible later needs. Once adequate tissue has been generated, the framework is reconstructed with carved costal cartilage. Some exaggeration of the bulk of the infrastructure minimizes distortion because it conforms to the cartilage. Silicone and other synthetic frameworks give excellent initial results, but they are fraught with late complications. In general, autologous tissues are recommended for ear reconstruction.

Periorbital area with expanded full-thickness grafts

The periorbital area contains skin that is soft and pliable. It contains few glands and no hair. Unfortunately, little tissue in the periorbital area can be expanded or moved easily. When large areas require reconstruction, full-thickness skin grafts from expanded donor sites are recommended. Replacement of aesthetic units – the entire periorbital area or the upper or lower lid – gives the best result (Fig. 25.11).

The supraclavicular area contains soft pliable skin that mimics orbital skin. Therefore, this is a good site for expanding, templating, and harvesting tissue subcutaneously, above the platysma. After harvesting, the expanded skin graft is thinned to dermis and sutured to the recipient site (see section on [expanded full-thickness skin grafts](#)). Long-term results have been remarkable in that this tissue grows with children, scarring is minimal, and secondary reconstruction is infrequent.

Reconstruction in the breast, chest, trunk, and extremities

Post-mastectomy breast reconstruction

Tissue expansion was introduced by Chemar Radovan in 1982 to facilitate breast reconstruction in post-mastectomy patients because these patients were found to have insufficient chest wall tissue for placement of the implant.⁷ Originally, the expanders were placed subcutaneously, but results from these reconstructions tended to be firm and round with a less-than-ideal cosmetic appearance. As the procedure became more widely accepted, surgeons preferred subpectoral and submuscular placement of implants. Breast reconstruction techniques have continued to evolve over the last 40 years and, with refinements in the techniques for autologous tissue transfer, the aesthetic standards for breast reconstruction have increased. Tissue expansion allows ideal color and texture match of the reconstructed breast with the remaining chest wall because the breast is generated from existing chest wall skin. Tissue expansion is a much simpler option for breast reconstruction than the more complex procedures used in autologous tissue transfer.

Use of tissue expansion and breast implants remains the most common method for post-mastectomy reconstruction in the US. Four factors account for widespread use of this technique: (1) continued refinements in surgical technique for mastectomy; (2) preservation of the pectoralis major muscle and its innervation; (3) less radical excision of skin with skin-sparing mastectomy; and (4) preservation of the inframammary fold. Because of these practical techniques, more reconstruction cases in patients with qualitatively good chest wall skin and soft tissue are suited to expansion techniques.

Placement of a tissue expander for breast reconstruction is a simple, straightforward procedure. In the case of immediate reconstruction, it adds little operative time after mastectomy and does not prolong the post-mastectomy hospitalization. Delayed reconstruction with a tissue expander can be done as an outpatient procedure or with minimal hospitalization. Furthermore, it is ideally suited to both elderly patients and those who wish to have a minimal postoperative recovery.

Breast reconstruction with the tissue expansion technique usually requires two operative procedures. In the first procedure, the tissue expander is placed through the original

mastectomy scar, thus avoiding additional scarring. Removal of the tissue expander and placement of the permanent implant are also accomplished through a straightforward approach and can be done under general or local anesthesia in an outpatient setting. However, if the expander is less than ideally positioned, the second procedure will be more complicated, requiring capsulotomy or capsulectomy. The reconstructed breast will experience some shifting and settling after placement of the permanent implant, so it is usually best to delay nipple reconstruction for several months.

Recreation of the inframammary fold and natural breast ptosis remains a difficult aesthetic goal. The location of the expander – whether it is better placed subpectorally or entirely submuscularly – is therefore a frequently debated topic. The use of acellular dermal matrix (ADM) to cover the lower pole of the implant expander was introduced in 2005⁴⁹ and has gained in popularity in recent years because it obviates the need for dissection of the serratus anterior. This results in less implant displacement during expansion.

The breast expander device

The original breast expanders were smooth-walled silicone devices with a remote port. Placement of the remote valve often proved tedious and, if not perfectly placed, resulted in mechanical filling difficulty. More recently, expanders with integrated valves have become the expanders of choice in breast reconstruction.^{50,51} The valve is located in the upper pole of the breast. Because an inflation needle can puncture an expander, the valve is easily palpable and has a metal backing to prevent injury to the attached expander. The integrated valve avoids the need to create a separate lateral pocket and subcutaneous tunnels for the connecting tube. It avoids the complications associated with a distal port, including rotation and extrusion of the port, and mechanical problems related to the connecting tubing such as kinking and leaking.

The textured silicone implant has been an important advance in breast reconstruction with tissue expansion. A textured surface enables tissue ingrowth and adherence of the capsule, which, in turn, immobilizes the implant. It is imperative that the textured expander be ideally positioned. The immobility of the textured implant enables development of two aesthetic benefits: a more anatomic expansion of the overlying tissue and more expansion in the inframammary fold area that helps establish a fold with some degree of ptosis.

Expander devices are generally described as round or anatomic. Each device is designed to allow for a more natural breast reconstruction by providing unique differential expansion of the upper, middle, and lower poles of the breast. In our experience, however, two other factors determine the final outcome more than the expander shape does: the quality of the skin and subcutaneous tissue and the preservation of the inframammary fold after mastectomy.

Immediate breast reconstruction

The inframammary folds should be marked with the patient sitting in an upright position before general anesthesia is induced for mastectomy and placement of the expander. The mastectomy should be accomplished in a fashion that maximizes local control, with careful attention, however, to preservation of skin and subcutaneous tissue, especially in the inframammary fold area. In recent years, with the

optimization of skin-sparing mastectomy and development of nipple-sparing mastectomy, general surgeons are much more conscientious in preservation of the skin. If too much skin is spared, the plastic surgeon will need to trim excess skin that could cause dog-ears and sagging; this is done after placing the expander.

After completion of the mastectomy, the expander is placed in one of three locations, depending on the surgeon's preference and experiences. These are the total submuscular position, the subpectoral (dual-plane) position, and the subpectoral position with supplementation with an ADM.

Complete muscle coverage is more important in immediate than in secondary breast reconstruction because it completely isolates the implant from the overlying mastectomy wound. Should there be skin necrosis with a loss of mastectomy flaps, wound dehiscence, delayed healing – especially in previously irradiated chest walls – or cellulitis, a totally submuscular implant may be salvaged, whereas a partially submuscular implant will be lost.

After placement of the implant by one of these three methods, suction drains are placed in the subcutaneous space and in the axilla if a lymph node dissection has also been completed. The wounds are closed in layers and the expander filled with enough fluid to obliterate dead space, but avoiding excessive tension on the wound closure.

Submuscular position

When the submuscular position is used for expansion, a submuscular pocket is dissected for placement of the tissue expander. The muscle incision can be made in one of two locations. If a musculofascial layer has been preserved after mastectomy, the incision can be made parallel to the pectoralis major fibers. Using sharp and blunt dissection, the pectoralis major muscle is lifted off the underlying chest wall and the pectoralis minor muscle. Dissection is continued inferiorly beneath the origin of the rectus abdominis muscle and laterally beneath the serratus anterior muscle.

Alternatively, an incision can be made at the lateral border of the pectoralis major or parallel to the fibers of the serratus anterior muscle. This dissection is continued down to the rib, and from the lateral position, a pocket is dissected inferiorly, superiorly, and medially, lifting the pectoralis major origin off the rectus abdominis muscle and the origin of the serratus anterior muscle.

It is important to avoid dissecting the serratus anterior muscle too far laterally, regardless of the location of the muscle incision, for this would allow displacement of the implant into the axilla. If the fascia at the junction of the pectoralis major and rectus abdominis muscles has been violated during mastectomy, complete submuscular closure can be difficult. In general, a small exposure of the implant is of no consequence. A large exposure can be covered with a transposition or rotation of anterior rectus abdominis fascia.

Subpectoral (dual-plane) position

Only the upper two-thirds of the expander in the subpectoral (dual-plane) position is covered by muscle. Advantages include less postoperative discomfort and less discomfort during expansions. Criticisms of this technique include the risk of upward migration of the pectoralis major, which results in even less coverage of the lower portion of the implant. If

there is wound breakdown at the mastectomy incision, the implant, rather than muscle, will be exposed.

The inferior border of the pectoralis major is identified, the pectoralis fascia is incised if it has been preserved, and the muscle is elevated while preserving the origin of the serratus anterior and rectus abdominis muscle. The expander is introduced so that it lies in a dual plane with its upper pole covered by muscle and its lower pole solely by subcutaneous tissue.

Subpectoral position with an ADM

An ADM can be used to extend the subpectoral pocket, creating a hammock effect below the implant that provides an aesthetic inferior pole and inframammary fold, as well as soft-tissue coverage (Fig. 25.12).^{51–56} The hammock, or sling,

Fig. 25.12 (A) Tissue expanders for breast reconstruction are usually placed beneath the pectoralis and serratus muscles. **(B)** It is possible to place the prosthesis under the pectoralis major, where the muscle covers only the top half of the prosthesis, when a dermal matrix is sutured to the lower half of the pectoralis muscle and the chest wall to cover the lower half of the prosthesis.

Fig. 25.13 The technique of designing a ptotic breast by moving the inframammary fold. **(A)** The prosthesis is over-expanded to make an excess amount of tissue. **(B)** The position of the desired breast fold (point B) is determined on the thoracic wall. **(C)** Through an inframammary incision at point C, the expander is removed and a permanent device is placed. The skin and soft tissue (point A) are moved superiorly and sutured to point B. **(D)** The abdominal wall is undermined above the fascia and advanced into the inframammary defect.

holds the expander in place, minimizing the risk of downward migration of the implant. Further, the expander is less restricted than when it is completely submuscular, so expansion can progress more rapidly before placement of the permanent implant. In non-irradiated patients, human acellular dermis is re-vascularized and remodeled into the host tissues.⁵⁷ A number of human ADMs are commercially available. The ADMs are expensive and their cost must be considered when planning the best reconstructive course. Another disadvantage of using ADMs is that they also promote serous drainage, requiring drains to be maintained until serous drainage is less than 30 cc/day.

The pectoralis major muscle is elevated as described above. A sheet of ADM is sutured to the fascia overlying the rectus abdominis muscle at the planned inframammary fold. The size of the matrix is determined by the diameter of the chest wall and elasticity of the chosen dermal matrix. Typical sheet sizes vary from 4×12 cm to 6×16 cm. The expander is introduced beneath the pectoralis superiorly and the ADM inferiorly and the muscle and superior edge of the ADM are approximated. Drains are placed to accommodate serous drainage. If there is breakdown of the mastectomy wound, the underlying matrices will become exposed. Our preferred management of this complication is early excision of ischemic skin and re-closure of the wound.

Delayed breast reconstruction with tissue expansion

As with immediate reconstruction, it is important to mark the inframammary fold and the extent of undermining while the patient is sitting in an upright position before induction of anesthesia. The tissue expander may be placed in one of the three pockets described above for immediate placement after mastectomy.

Inflation follows the general plan for expansion as previously described. Inflation of the expander is initiated 10–14 days after placement. The patient returns weekly or biweekly for serial percutaneous inflations. A 23-gauge butterfly needle is used with a distal port and a 21-gauge needle is used

with an integrated port. Care is taken not to overinflate the expander, causing unnecessary discomfort. The expander should be inflated until the overlying skin and subcutaneous tissues feel firm. If the patient experiences significant discomfort, saline is withdrawn until the patient is comfortable. With each inflation, the overlying skin frequently becomes hyperemic, but the problem usually resolves after inflation has been completed. After volumetric symmetry with the opposite side is achieved, hyperinflation of the expander is often carried out. If a large amount of ptosis is to be developed or extensive repositioning of the breast is necessary, additional hyperinflation may be required. Expanders may be left in place for many months or even years before being exchanged for permanent implants and this principle is also applied in the management of adolescent hypomastia.¹³

Repositioning of the inframammary fold can influence breast ptosis and definition. Increased ptosis is created by infolding and uplifting the expanded tissue and advancing a lower abdominal flap.^{58,59} After removing excess saline to determine the appropriate, symmetrical volume of the reconstructed breast, the inframammary fold is moved up or down so that the apices of the breasts are at an equal level. The new position of the fold is marked so that the reconstruction can be accomplished through an incision at the desired inframammary fold (Fig. 25.13). The capsule is left intact unless the prosthesis needs to be repositioned. Stable reconstruction of the inframammary fold can be achieved by tacking the interior capsule to the posterior chest wall capsule at the same level where the earlier, symmetrical marking was made. The abdominal skin is undermined above the fascia and is advanced superiorly into the inframammary cleavage to close the posterior wall defect (Fig. 25.14).

Tissue expansion in cases of chest wall irradiation

Studies suggest that previous chest wall irradiation negatively affects success with tissue expansion and subsequent implant placement.^{60,61} The complication rate due to infection, extrusion, and wound complications is higher. Furthermore, the

Fig. 25.14 (A) A patient after modified radical mastectomy with preservation of the pectoralis muscle. (B) An expander was placed beneath the pectoralis and serratus muscles and then gradually over-expanded. At a second procedure, a permanent implant was placed and a ptosis procedure was performed on the opposite side.

final aesthetic result is frequently compromised by capsular contracture.

Two groups of patients are probably best managed with autologous tissue transfers instead of with tissue expansion. They are those undergoing: (1) mastectomy for recurrence of disease after previous lumpectomy and radiation; and (2) secondary reconstruction after mastectomy and radiation. In selected patients with excellent-quality chest wall skin and soft tissue, tissue expansion may be considered even though the incidence of complications and a compromised aesthetic result are high.

Chest wall irradiation treatment is increasingly frequent in post-mastectomy patients. A large number of women who have undergone placement of a tissue expander at the time of mastectomy now have to deal with postoperative radiation. There is no consensus at this time on how to manage these patients. Alternatives that have been presented include the following:

1. Continue expansion until the time of irradiation, but cease inflating the expander during and for several months after irradiation; then resume expander inflation once the radiation dermatitis has resolved and follow with placement of the permanent implant.
2. Complete expansion and exchange with the permanent implant and then proceed with radiation.
3. Remove the fluid in the expander, initiate and complete radiation therapy, and then re-inflate the expander once tissues have begun to heal.
4. Remove or maintain the tissue expander and make plans for autologous tissue reconstruction after radiation is complete.

Despite the above risks, more than 50% of patients are reported to have satisfactory results if tissue expansion is completed alongside treatment with radiation.⁶¹ Patient education about risks and alternatives is critical and there must be an understanding of these different options/strategies before any reconstruction is initiated in patients receiving radiation for breast cancer treatment.

The hypoplastic breast

Tissue expansion has played an important role in the reconstruction of both acquired and congenital breast

hypoplasia. Management of the deformity depends on the degree of breast asymmetry, the nature of the deformity, the quality of the chest wall soft tissue, and the age of the patient at presentation.

Unilateral hypoplasia varies from a smaller, well-formed breast to total absence of the breast. These cases further have variable hypoplasia or aplasia of the nipple and areola. If a hypoplastic nipple–areola complex is present, it will usually lie in a cephalad position relative to that of the contralateral breast.

The degree of breast hypoplasia is determined and characterized as minor hypoplasia with a normal nipple–areola complex, moderate to severe hypoplasia, or total breast aplasia. The nipple–areola complex is characterized separately as normal, hypoplastic, displaced, or aplastic. Mild breast hypoplasias may be corrected with simple placement of a breast implant, but more severe hypoplasias and aplasias with nipple–areola displacement are best treated with initial placement of a tissue expander. If pre-surgical examination reveals that the pectoralis muscle is absent, the deformity is probably associated with Poland syndrome (see below).

A tissue expander is placed through either an inframammary or axillary incision into the subpectoral space. The surgeon may choose from many expanders: these include smooth and textured implants, implants with integrated valves, and expanders with distal ports. The prosthesis is initially expanded at 2-week intervals. As the expander is inflated and the overlying skin relaxes, the cephalad-displaced nipple–areola complex will descend. The more slowly the expander is inflated, the better the nipple–areola will descend. A slow expansion also minimizes development of striae. The expander is ultimately overinflated to a volume that is at least 40% larger than the desired volume of the permanent implant. The expander is left in place for several months after the final inflation to allow development of additional ptosis.

The permanent implant is introduced at a second procedure. An incision is made through the original incision that was made to place the expander. The expander is removed, and a capsulectomy is carried out, if needed. If capsulectomy is not needed, the inferior portion of the capsule may be tacked to the rib periosteum to delineate the inframammary fold better. A permanent implant is selected to achieve symmetry with the contralateral side.

Reconstruction with a permanent expander prosthesis is also possible. This prosthesis is inflated to a size several hundred milliliters larger than the desired final volume. The expander prosthesis is allowed to remain overinflated for several months. In the office, saline is then withdrawn to achieve symmetry with the contralateral breast. When desired, the port with its attached tubing is removed through an incision made over the distal port.

The tuberous breast

Expansion is a useful technique in the correction of the hypoplastic tuberous breast. Through an inframammary or periareolar approach, the tuberous breast is lifted off the underlying pectoralis fascia. Radial cuts are made through the breast tissue to expand the base of the breast, and a tissue expander is introduced in the submammary plane. Inflation and expansion are achieved as previously discussed. Once adequate expansion has been achieved, the expander is removed and replaced with the permanent prosthesis. Alternatively, a permanent expander device is used and overinflated by several hundred milliliters. Several months after completion of the inflation, fluid is removed to achieve symmetry with the contralateral side, and the port and attached tubing are removed.

The immature breast

The use of tissue expanders has been beneficial in the management of young adolescents presenting with breast asymmetry.⁶² Adolescence is a critical time that is characterized by intense social pressures and self-awareness of a developing physique, so failure to address the problem of breast asymmetry can result in psychological problems. These patients do not need full maturity for reconstruction.

A subpectoral muscle plane is elevated through a small axillary incision. An expander with an integrated valve or distal port is placed in the subpectoral plane beneath the hypoplastic breast. If a distal-port prosthesis is used, the inflation reservoir is placed in the lateral thoracic wall or in the upper abdomen below the inframammary fold. The prosthesis is then inflated at intervals appropriate to maintain symmetry with the developing breast on the contralateral side. The slow expansion will cause the areola to enlarge, and the nipple–areola complex will progressively be displaced caudally to a more normal position. The adolescent can continue with normal activities, participation in sports, and other physical endeavors.

Once development of the contralateral breast has stabilized, usually between 18 and 19 years of age, the expander is removed. Definitive reconstruction is achieved as previously described for correction of the mature breast.

Correction of Poland syndrome

Poland syndrome involves not only abnormal development of the breast but also thoracic wall deformities, deformities of the upper extremity, and vertebral anomalies. Poland syndrome exhibits a uniform absence of the sternal head of the pectoralis major muscle. Further structural problems may be seen and include abnormalities in the anterior ribs and costal cartilages and deficiencies of the muscles of the scapular area, including the latissimus dorsi. Other findings include deficiency of subcutaneous tissue, hypoplasia, aplasia, or

malposition of the nipple–areola complex, and deficiency of breast tissue.

A mild deformity characterized by breast hypoplasia or aplasia is corrected with the initial placement of a tissue expander through a transaxillary approach. A 700-mL or larger expander may be required to achieve full expansion over a 3–4-month period. Then the tissue expander is removed and a permanent breast implant is placed. Ideally, if there is an inadequate anterior axillary fold and adequate latissimus dorsi muscle, it may be transposed to cover the breast prosthesis. Its insertion is taken down and transposed anteriorly on the humerus to form an anterior, axillary fold. Alternatively, the tissue expander can be placed at an initial operation and covered immediately with a latissimus dorsi muscle transposition. Once expansion has been completed, the expander is removed and the permanent breast implant introduced.

More severe cases of Poland syndrome that are characterized by contour depression of the ribs will require either an osteotomy and repositioning of the ribs or the use of a custom, solid, silastic implant. The anterior axillary fold is reconstructed by transposition of the insertion of the latissimus dorsi muscle over the custom silastic implant. The breast contour is reconstructed with tissue expansion and the subsequent use of a permanent breast implant.

In the immature girl with Poland syndrome, expanders are placed at the onset of contralateral breast development through a small incision in the axilla. To maintain aesthetically pleasing symmetry, the implant is gradually inflated until development of the contralateral breast has stabilized. In the final months of treatment, the expander is overinflated by 200–300 mL and then replaced with the permanent implant. If a latissimus dorsi muscle is available, it is transposed at this time to cover the breast prosthesis (Fig. 25.15).⁶²

Expansion of the trunk

The trunk and abdomen are well suited to tissue expansion in individuals of all ages. Because of the large adjoining surface area from which tissue can be recruited, large prostheses can be placed and flaps quickly expanded (Fig. 25.16). Expansion of the trunk with large prostheses may produce significant deformity and discomfort. Expansions of the back and buttocks are particularly difficult for the patient because of their interference with activities of daily living. Fortunately, using multiple prostheses in such areas produces sufficient tissue for completion of the reconstruction, minimizes distortion, and allows rapidly expedited expansion.

Large prostheses can be either placed above the fascia or incorporated between fascia and muscle planes in the abdomen or on the back. Incorporation of any of the latissimus dorsi, pectoralis major, or rectus muscles allows development of an expanded myocutaneous flap. Prostheses placed between layers of the abdominal wall have been used to develop large flaps for abdominal wall reconstruction (Fig. 25.17).⁶³

Large deformities, such as burns, giant hairy nevi, and other congenital anomalies, may require multiple serial expansions. In such cases as these, the expanders are inflated maximally and the flaps are advanced. The prostheses are left in place and re-expansion is carried out in the subsequent weeks. In the abdomen, two or three serial expansions are usually well tolerated, even in children.

Fig. 25.15 (A) This 17-year-old patient presented with severe right breast hypoplasia with nipple hypoplasia and superior malposition of the right nipple as a feature of her Poland syndrome. (B) She underwent the subcutaneous placement of a tissue expander beneath the skin and soft tissues of the right breast to expand the soft-tissue envelope and increase the distance from the clavicle to the nipple. A latissimus dorsi muscle flap was harvested using two small incisions on the back and single incisions in the axilla and inframammary region of the breast. (C, D) The muscle was transposed to the chest through a high axillary tunnel and placed beneath the expanded soft-tissue envelope and anchored to the parasternal area and inferior aspect of the expanded breast envelope. (E) An implant was placed beneath the muscle to provide the necessary volume to the breast reconstruction, producing an immediate and (F) long-term improvement of the breast appearance at 3-year postoperative follow-up. (G) This produced an excellent change in the breast appearance at 3-year follow-up after surgery. (This case courtesy of Julian J. Pribaz MD. Reproduced from Hall Findlay E, Evans G. *Aesthetic and Reconstructive Surgery of Breast*. Edinburgh: Elsevier Saunders, 2010. © Elsevier 2010.)

Fig. 25.16 (A) Separation of ischiopagus twins was aided by first expanding both the anterior and posterior trunk skin. (B) At a second procedure, the hemipelvis of each side was brought together with the opposite side by closing the pelvic ring over expanded soft tissue. Soft tissue was adequate to achieve total closure in both infants. The children have now survived over 10 years since separation and are doing well.

Fig. 25.17 (A) A ruptured omphalocele including the liver had failed reconstruction on two attempts. (B) The abdominal contents were enclosed in Alloderm™ and a vacuum-assisted closure dressing placed over it to colonize it with granulation tissue. When adequate granulation tissue had been developed, a cultured split-thickness skin graft was placed over the entire defect. (C) At 4 years of age, expanders were placed beneath and lateral to the rectus muscle to generate adequate skin and muscles for abdominal closure. (D) The viscera was reduced to the abdominal cavity and the rectus muscles were brought together in the midline to create a stable abdominal wall. The patient has remained stable for 7 years without further surgery.

Expansion in the extremities

Skin and soft tissues of the extremities tolerate tissue expansion well,⁶⁴ so tissue defects resulting from congenital abnormalities, tumor, or trauma may be corrected. The capsule that develops adjacent to the expander has a resilient surface that can be transposed over joints and tendons to decrease adhesions.

The use of multiple expanders in the extremity has the advantages of less distortion, less compromise of everyday life activity, and more rapid development of tissue. Standard rectangular and round prostheses usually suffice and they are best placed axially to the defect. Functional impairment, even when the prostheses are placed directly over vessels and nerves, is unusual. Occasional transitory neuropraxias have been described in the lower extremity but are uncommon in the upper extremity. If such discomfort or neuropraxia develops, the prostheses should be deflated and then re-inflated at a much slower rate.

In areas such as the hand or foot, custom implants may be fabricated. The dorsum of the hand or foot lends itself well to expansion, whereas the palm and plantar areas are particularly painful during, and resistant to, expansion. Expanded full-thickness grafts harvested from the abdomen are extremely versatile in reconstruction of the foot and hand. These grafts are stable and can be harvested as a single graft. Reasonable protective sensation returns to these grafts over time.

The upper leg is easily expanded because of the thickness of skin and its underlying subcutaneous tissue: one large expander or multiple smaller expanders may be used. Complications are infrequent. However, below the knee, inflation carries major risks. Clean, isolated defects, such as those that follow local tumor excisions, are more amenable to expansion than sites where large areas of previously traumatized skin surround the defect. Multiple small expanders are recommended to minimize the risks of implant loss. If cellulitis or tissue compromise occurs during expansion, the prosthesis should be deflated or removed.

Lower leg expansion after crush injuries carries particularly high risk. Individuals who have suffered major crush or degloving trauma to the extremity are better treated with function-restoring microvascular and myocutaneous flaps than with attempts at excessive aesthetic reconstructions using tissue expansion.

Wound management with negative pressure therapy

Negative pressure wound therapy (NPWT) uses the principle of applying mechanical force to cells surrounding a wound to stimulate the induction of new tissue development that will subsequently aid in closure of that wound.³

Historical perspective

The use of vacuum forces on wounds was described in 1995 by Fleischmann who employed the technique of placing suction drains wrapped in porous polyvinyl alcohol foam into wounds.⁶⁸ These wounds were sealed with polyurethane drapes and then the drains were attached to a suction apparatus at 600 mmHg. In 1997, Drs. Argenta and Morykwas at Wake Forest University presented their experience with vacuum-assisted closure (VAC) devices.³ They presented the use of the VAC in 175 chronic wounds, 94 subacute wounds,

and 31 acute wounds over a nine-year period in conjunction with their animal study experience over the same period. Clinically, the application of negative pressure causes the dressing sponge to collapse towards its center producing deformation and traction forces applied to the wound perimeter pulling the wound edges together which progressively make the wound smaller. In addition, NPWT removes wound edema, appears to increase circulation and decrease bacterial counts, and significantly increases the rate of granulation tissue formation.⁶⁹

Cellular and molecular basis of NPWT

The mechanical effects of NPWT on wounded tissues and their subsequent cellular and molecular effects are actively being studied. At a cellular level, NPWT alters wound bed gene expression with resultant changes in cytokine/chemokine/growth factor expression and matrix metalloproteinase (MMP) expression. In human and animal models, increases in anti-inflammatory cytokines (IL-10) and pro-angiogenic growth factors (VEGF, FGF, PDGF) have been demonstrated with the use of NPWT. The above, in conjunction with reduction in MMP expression, indicates that NPWT may promote healing by modulation of cytokines to an anti-inflammatory profile and alteration in mechanoreceptor- and chemoreceptor-mediated signaling to culminate in angiogenesis and extracellular matrix remodeling for the deposition of granulation tissue.¹⁸

The vacuum-assisted closure (VAC) device

The basic VAC system consists of sponge material composed of reticulated polyurethane or polyvinyl alcohol (white foam) cut to fit the wound, an occlusive drape, suction tubing, and adjustable vacuum pump with a collection canister. Since its introduction, many technologic improvements have been made, making this technique more user-friendly. Advances include smaller device and battery, the ability to modulate pressures applied to the wound, improved fluid management capabilities, the availability of different types of foams to be tailored to wound characteristics, and the addition of safety precautions/leak alerts to the device.⁶⁵

Patient selection

Vacuum-assisted closure devices were initially designed for the management of chronic wounds such as diabetic ulcers, venous stasis ulcers, and pressure ulcers in order to simplify wound care in this patient population or bridge wounds until factors preventing definitive wound reconstruction could be resolved or improved. Today, this technique can be safely applied to all patient populations and in a wide range of acute or traumatic soft tissue injuries including wounds with compromised soft tissues, contaminated wounds, hematomas, and gunshot wounds.

Despite the myriad of clinical scenarios where a VAC can be utilized, there are specific contraindications to its use. It should not be used when hemostasis is inadequate as the negative pressure may continue to remove blood from an actively bleeding or oozing wound. NPWT application should be avoided if necrotic or sloughing tissue is present. In general, prior to application of NPWT, aggressive surgical debridement of all nonviable tissue and any foreign body is performed, appropriate coverage of critical structures is completed (major

vessels, viscera, nerves) utilizing local muscle or soft tissues, and then NPWT initiated.

NPWT technique

Negative pressure wound therapy requires placement of a sponge material on or into the wound. An occlusive drape is then placed over the sponge and onto the surrounding skin. An opening is made in the occlusive drape, and the suction tubing is fixed to the exposed sponge with an occlusive seal. The suction tube is attached to the collection canister which is attached to the adjustable vacuum pump. The vacuum pump can be used as continuous or intermittent vacuum using pressures of 75 to 125 mmHg when using polyurethane foam and as higher continuous pressures of 125 to 175 mmHg when using polyvinyl alcohol foam. VAC foam dressing can safely be changed at 2 to 3 day intervals. At the time of foam change, other traditional wound healing modalities, such as pulse lavage, can be used. Silver-impregnated foam sponge has been introduced to provide a bactericidal sponge in patient with colonized wounds. This technique is continued until the goal of wound closure is achieved or the wound undergoes elective reconstruction with standard techniques.

Special considerations

Decompressive fasciotomy wounds

NPWT may be employed in the management of wounds following decompressive fasciotomy. With negative pressure, the edematous muscle and soft tissues are decompressed rapidly over a period of 2–3 days. The interval between fasciotomy and wound closure may be lessened with this technique and may increase the likelihood of primary closure rather than skin grafting, which has been the traditional method of management of fasciotomy wounds treated with daily saline dressing changes.

Skin grafting/dermal substitutes

Vacuum-assisted closure provides an alternative method with which to bolster a skin graft or dermal substitute.⁷⁰ The sponge is cut to conform to the wound and, when the air is withdrawn from the sponge, the firm sponge serves as a stent that maintains the graft/ substitute in place during the process of revascularization. Furthermore, the negative pressure therapy aids in neovascularization providing a better wound bed for full thickness skin grafts, dermal substitutes,⁷¹ and grafts on the diploic layer of bone with little granulation.

Acute burns

Morykwas showed in a swine model that NPWT decreases burn wound progression.⁷² This is likely due to the removal of edema fluid allowing for improved blood flow into the burn wound environment. This in turn minimizes tissues in the zone of stasis progressing to the zone of coagulation with subsequent tissue necrosis. When applied to hand burns, NPWT results in more rapid reduction of hand edema allowing improved physical therapy and hand mobility.

Incisional VAC application

The collapsed VAC sponge does not traumatize a fresh wound closure or a fresh flap. During the first 24 hours after wound

closure the wound is not yet sealed, and the VAC is beneficial in drawing serous fluid from between the sutures of the closure. It may be applied over a fresh flap and does not result in any compromise to the underlying flap. Recently, application of NPWT to incision closure has been more frequently employed. There is a growing body of literature that demonstrates reduced incidence of wound healing complications with the use of incisional wound VAC application for a period of 3–5 days.^{73,74}

Postoperative care

In general, expanders should be partially inflated immediately after wound closure. This allows closure of “dead space” to minimize seroma and hematoma formation. It also smooths out the implant wall to minimize risk of fold extrusion. Enough saline is placed to fill the entire dissection space without placing undue tension on the suture line.

Serial inflation usually starts 1–2 weeks after initial placement, although inflation schedules can be individualized to the specific case and the tolerance of the patient. Inflation reservoirs seal best when a 23-gauge or smaller needle is used. A 23-gauge butterfly intravenous needle is especially useful; it allows the patient to move slightly without dislocating the needle. Frequent small-volume inflations are better tolerated and are physiologically more suited to the development of adequate overlying tissue than are large infrequent inflations.

For practical purposes, most prostheses are inflated at weekly intervals. On occasion, accelerated inflation schedules may be followed.⁴¹ In children who have devices with external ports, small-volume inflation at 2–3-day intervals is well tolerated. Individual inflations proceed until the patient experiences discomfort or blanching of the overlying skin. In hypoesthetic areas, objective changes in flap vascularity must be evaluated with particular care. Although a variety of devices such as pressure transducers and oxygen tension monitors are available to help determine proper inflation, an objective evaluation of the patient's response is usually a reliable indicator of appropriate inflation. Serial inflations proceed until an adequate amount of soft tissue has been generated to accomplish the specific surgical goal.

Specific to breast tissue expansion, the frequent visits required to inflate the expansion device fully create some inconvenience for patients, who are seen every 7–14 days. This process usually continues for 2–3 months, depending on the desired final size of the implant. Overinflation is helpful when permanent breast implants are to be placed. Inflation of breast expanders by 20% over capacity is commonly performed so that after the permanent implant is placed, some ptosis of the breast can be developed.

Complications and their management

Initial attempts at tissue expansion were associated with a high rate of complication which included, but were not limited to, implant failure due to either puncture during inflation or mechanical problems. As more experience accumulated, however, the incidence of complications dramatically decreased. Complication rates are directly proportional to the number of expansion procedures performed and the experience of the individual surgeon.⁶⁶ Most complications incurred

during tissue expansion are relatively minor and do not interfere with completion of multistage procedures.

Implant failure

Despite design improvements, the use of an excessively large needle or the inadvertent puncture of the implant can lead to implant deflation. To maximize sealing of the valve, the implant reservoir should be entered at a 90° angle. If there is any question about the location of the inflation reservoir, radiologic or sonographic techniques may be helpful.

Infection

As with the placement of any prosthetic device in the human body, infection is possible. The introduction of bacteria to the wound in the perioperative period is the most common cause of early infection. The area to be reconstructed should be stable, and there should be no open wounds at the time that the procedure is undertaken. Areas susceptible to lymphedema, such as traumatized lower extremities, carry a significantly higher rate of infection. An area of copious lymphatic drainage, such as the neck or the groin, also tends to accumulate lymphatic fluid around a prosthesis and is more susceptible to infection. These areas should be drained with suction drains until all excess drainage stops. Antibiotics are given as long as the drain remains in place.

Late infections are usually caused by iatrogenic introduction of bacteria during the course of inflation. The inflation procedure should be performed under sterile conditions in the office. Povidone-iodine (Betadine®) is used to prepare the injection site. Externalized distal ports carry a high colonization rate, but the resultant contamination produces little complication. Many infections can be difficult to detect and can be tolerated well by the patient.⁶⁷

Some erythema may occur over all expansion prostheses; however, pain, warmth, and systemic symptoms such as fever and chills suggest clinical infection. If the infection occurs in the perioperative period or early course of expansion, the prosthesis should be removed and the wound irrigated. The

procedure is aborted, and a second attempt is made 3 or 4 months after healing. If infection occurs late in the course of expansion, the prosthesis can be removed and the expanded tissue advanced after irrigation of the infected cavity. Permanent implants should not be placed when Gram stain of the expander space reveals bacteria.

Implant exposure

Implant exposure can occur both early in the postoperative period and after a protracted course of expansion. Treatment of the exposed implant depends on the timing of exposure. Exposure early after placement is usually related to inadequate dissection or use of an excessively large prosthesis that abuts on wound closure. If the prosthesis becomes exposed soon after placement, it is best to remove it and re-operate 3–4 months later.

Late exposure is usually related to excessively rapid or overzealous inflation. Rapid expansion is medically necessary only in few instances. Tissue expansion should be carried out judiciously to achieve optimal cosmetic results. If minimal or late exposure occurs during the course of expansion, the procedure can continue with the use of antibiotic creams on the exposed area. In this situation, multiple, rapid fillings are done to generate adequate tissue. Reinforcement of the compromised overlying skin with paper tape is sometimes helpful. Most flaps survive and do well even with some exposure of the implant.

In compromised tissues, such as grossly traumatized lower extremities or irradiated and burned tissues, the use of tissue expansion can more easily result in implant exposure – a cautious approach is warranted.

Compromise and loss of flap tissue

Tissue expansion exerts changes on living tissue similar to those seen in the phenomenon of conventional flap delay.²⁹ Expanded flaps are almost universally more robust than non-expanded flaps. To ensure vascularity, one should attempt to maintain a major axial vessel in the expanded tissue.

Principles of radiation

Gabrielle M. Kane and Gurleen Dhami

 Access video lecture content for this chapter online at expertconsult.com

SYNOPSIS

- Radiation therapy (RT) can be used as a primary or adjuvant treatment for many cancers.
- The unit of dose measurement is the gray (Gy).
- Side effects are characterized as acute and late toxicities.
- Acute toxicities are temporary and reversible.
- Late toxicities are permanent.
- The primary mechanism of action of radiation is through breakage of DNA strands.
- Treatment planning is achieved through use of three-dimensional computed tomography (CT) planning.
- Delivery of radiation can be very precise with the use of intensity-modulated radiation therapy (IMRT) as well as with image-guided radiation therapy (IGRT).

Access the Historical Perspective section online at

<http://www.expertconsult.com>

Introduction

Radiation therapy (RT) requires an understanding of physics. A multidisciplinary team, including radiation oncologists, physicists, dosimetrists, and radiotherapists, is required for the delivery of radiation. Delivery of radiation can be achieved using different modalities, including kilovoltage, orthovoltage, megavoltage, electrons, protons, and brachytherapy.

RT utilizes ionizing radiation to treat malignant tumors and some benign disorders. Nearly two-thirds of cancer patients receive RT as part or all of their treatment. Radiation oncology is the discipline of medicine that addresses the causes, prevention, and treatment of human cancer with special emphasis on the role of ionizing radiation.⁴ Radiation oncologists work in a multiprofessional team with radiation therapists, nursing, dosimetry, and medical physics, along with dietitians, social workers, and counselors. Radiation therapists are the technologists who deliver the RT; they

spend not only considerable time on the technical components of treatment (treatment delivery, quality assurance, and verification), but also interact with and support cancer patients throughout the duration of their therapy. Radiation oncologists work with surgical and medical oncologists, diagnostic radiologists and pathologists, and are essential participants at tumor board for multidisciplinary decision-making. Outside the immediate team, it is rare for other physicians to know much about the technology, process, rationale, and issues around RT, and even less about the risks and causes of toxicity. This chapter is designed as a primer, or virtual elective in the topic, and aims to improve communication and understanding between plastic surgeons and radiation oncologists so that they can better appreciate some of the common issues faced when caring for cancer patients. This chapter starts with a brief description of the basics of radiation technology, modalities, medical physics, and radiobiology. It then outlines practical applications, with a description of RT planning and process, and clinical treatment issues for select cancers. The final section describes specific toxicity syndromes.

Radiation technology

RT has consistently relied on technology. Although much of the equipment that has been the mainstay of RT is being replaced by newer technology, some of it remains in effective and efficient use. For example, kilovoltage therapy can be effectively used for very superficial treatments. It delivers 100% of the prescribed dose at the skin, has rapid fall-off below the skin, and a tight penumbra (edge of the beam). In the 50–150-kV range, penetration provides useful coverage only to a depth of 5 mm; orthovoltage therapy (150–500 kV) provides better penetration, but is not capable of treating much more than 3 cm below the skin. With kV energies, skin dose becomes the rate-limiting step. At the orthovoltage range of energy, interaction between radiation and matter is strongly dependent on the atomic number (Z) of the attenuating material. For the photoelectric effect, high Z tissue, such as bone, attenuates more

Historical perspective

In November 1895, Wilhelm Conrad von Roentgen discovered a new type of ray that was generated from a stream of electrons in a cathode gas discharge tube and had the ability to pass through tissues with different degrees of penetration. Because the composition of the rays was unknown, they were called X-rays. His subsequent presentation to the Würzburg Society on the ability of his rays to generate an image of structures inside the body gave birth to diagnostic radiology. The following year, in France, Henri Becquerel discovered that fluorescent materials made of uranium also emitted constant radiation.¹ Marie and Pierre Curie used ionization to measure becquerel rays and quantify radiation intensity against uranium. Marie Curie first used the word “radioactivity” in 1898. The couple isolated two new radioactive elements from pitchblende, polonium, named for Marie’s native Poland, and radium, Latin for ray. Today, these pioneers’ names are in constant use as measures of radioactivity.²

The earliest oncologic brachytherapy procedure was in 1902, when a radium applicator was used to treat a tumor of the palate and pharynx. Within a few years, there were clinical studies of effectiveness, and radium tubes were inserted directly into tumors, and by the 1920s, radium had become the standard of care in oncology,³ as well as the treatment for many benign conditions. The use of Roentgen’s rays to palli-

ate advanced cancer was first described in 1903,⁴ and this was the forerunner of external-beam radiation treatment.

Until the 1950s, most radiation machines were very similar to diagnostic radiology ones, and generated X-rays at potentials of up to 300 kV. Superficial therapy (50–150 kV) could treat to a depth of 5 mm, and thus was useful for superficial skin cancers. Orthovoltage (or deep) therapy (150–500 kV) provided greater penetration, but was not capable of treating much more than 3 cm below the skin, with 100% of the dose at the skin. At this range of energy, interaction between radiation and matter is strongly dependent on the atomic number (Z) of the attenuating material – in other words, in this process, known as the photoelectric effect, tissue such as bone, which has a high Z, attenuates more radiation; fat and soft tissue (lower Z) attenuate less; and air (for example, in the lungs) hardly at all, thus producing the contrast necessary for diagnostic imaging. Unfortunately, this higher absorbed dose in bone resulted in many more problems from osteoradionecrosis (ORN).

The development in Canada of the cobalt-60 unit in 1951 introduced the new era of megavoltage (MV) radiotherapy to the world, allowing greater penetration of tissue and, with maximal dose not achieved until a depth of 0.5 cm, resulting in better skin-sparing and improved dose homogeneity. Since then, computer-controlled megavoltage linear accelerators have been developed, providing increasing penetration and skin-sparing, and a rapid accumulation of technologies to verify, deliver, and record increasingly precise RT.

radiation than lower Z tissue, such as fat and lungs, producing the contrast necessary for diagnostic imaging. Unfortunately, this higher absorbed dose in bone resulted in many more problems from osteoradionecrosis (ORN).

Megavoltage radiotherapy allows even greater penetration of tissue, resulting in better skin-sparing and improved dose homogeneity. It is not influenced by the atomic number of the absorbing medium, as Compton scattering is predominant in this energy range.

Cobalt units deliver MV radiation, and have a ^{60}Co source that generates gamma (γ) rays with average megavoltage energy of 1.25 MV. ^{60}Co has a half-life of 5.26 years, and as a result of this decay and subsequent drop in output, the source needs to be replaced every few years. Maximum dose (D_{max}) is not achieved until 0.5 cm beyond the surface of the skin and the intrinsic scatter of the beam and ionized particles means that the penumbra, or dose fall-off at the edge of a beam, is not very tight. Despite this, cobalt is still a prevalent and important external-beam radiotherapy modality, as it still provides an excellent low-maintenance, reliable, safe, and effective alternative in many low- and middle-income countries.

Photons are the most commonly used RT modality. They are generated by a linear accelerator, or linac, which uses high-frequency electromagnetic waves to accelerate electrons to a very high energy through an accelerator tube and beam transport system. When the accelerated electrons hit a high Z target at the end of this, they produce megavoltage X-ray beams that have sharper edges and can penetrate deep tissue. Typical photon energies produced by linacs are 4, 6, 10, and 18 MV that result in increasing maximum depth doses.

Particle therapy

Electrons are the most commonly used particle therapy. They are also generated by linacs by removal of the target in the beam's path for production of electron beams. Most linacs can produce a range of electron energies from 4 to 17 MeV. They deposit their energy superficially, sparing structures deeper in the body, with fairly steep dose distribution curves. Electrons produce more side scatter than photons and have wider penumbras. They are typically used to treat skin cancers, "boosts" to breast tumor cavities, and for intraoperative radiotherapy. They are also used to spare sensitive organs that may otherwise reach maximum tolerance, for example, protecting the spinal cord when treating posterior neck nodes.

Many new proton facilities are opening nationwide; they are expensive and cumbersome to construct and maintain, requiring a cyclotron or a synchrotron to accelerate protons, which have a mass nearly 2000 times that of an electron. Protons have similar biologic activity as photons; their advantage is that they have a unique shape to their dose distribution, with low steady-dose deposition until near the end of their clearly defined range when the dose peaks then falls sharply to nearly zero. This is the Bragg peak phenomenon, which allows very precise dose distribution, protection of critical structures, and dose intensification. By combining different beam energies, a spread-out Bragg peak (SOBP) is created which is able to encompass the target in its entirety to the prescribed dose. Protons are ideal for treating structures in the base of skull, such as the clivus, especially for chordomas, where the necessary dose is far above the tolerance of the sensitive optic chiasm

Fig. 26.1 Axial proton treatment plan for a spinal myxopapillary ependymoma with sparing of the bone marrow and anterior-lying organs. (Courtesy, Jason K. Rockhill MD PhD.)

and other sensitive structures in that region, and would otherwise cause severe toxicity, or for spinal cord tumors, such as ependymoma (Fig. 26.1). Another indication for protons is to deliver craniospinal irradiation for pediatric cancers such as medulloblastoma, because the proton dose distribution significantly reduces the exit dose to anterior structures (kidneys, bowel, lungs) when compared to conventional photon therapy (Fig. 26.2). Proton beam radiotherapy is useful for reirradiation as it often can reduce dose to critical structures that have

Fig. 26.2 Comparison of photon and proton craniospinal radiation treatment plans for pediatric medulloblastoma. Both techniques use a single posterior beam, but the proton plan has significantly less exit dose. (Courtesy, Ralph Ermoian MD.)

already been exposed to prior radiation. Proton beam radiotherapy is also utilized for the treatment of prostate cancer and shown to have high efficacy with minimal bowel and bladder toxicity,⁵ but long-term data are needed to compare late toxicity rates with photon beam RT. However, changes in tissue heterogeneity can affect where the particle stops and the position of the Bragg peak, leading to some uncertainty in dosing. Currently, there are several ongoing randomized trials that are evaluating the role of protons versus photons in respect to survival, toxicity, and quality of life outcomes. Some currently accruing trials include RTOG 1308 for inoperable non-small cell lung cancer and NRG-BN001 for glioblastoma.

Neutron RT, first used for cancer therapy in the 1930s, offers the advantage of high linear energy transfer, a property that allows the delivery of 20–100 times more energy along their path than photons, thus being biologically more effective in treating radioresistant tumors such as sarcomas and salivary gland tumors.¹ Their use requires a careful balance of risk and benefit as they can lead to more severe late toxicities.⁶

Carbon, neon, and heavier ions hold promise as they combine the radiobiological advantages of neutrons with the dose distribution and Bragg peak of protons, but are only available in select centers.

Brachytherapy

Brachytherapy, meaning “short distance” in Greek, is a method of delivering radiation treatment near or within a target using radioactive sealed sources. There are three main ways of delivering this type of radiation: (1) an applicator can be used to deliver dose to the surface of a thin tumor, for example, an eye plaque used to treat ocular melanoma; (2) intracavitary – inserting the sealed source into the cavity of an organ, e.g., in the treatment of cervical cancer, a combination (tandem) apparatus is used consisting of a cylindrical rod inserted into the cervical os and through the cervical canal into the uterus, with two ovoids placed in the lateral fornices; and (3) interstitial, when the source is either implanted directly into the tumor or postoperative bed, for example, for postoperative treatment of sarcoma, or when radioactive gold seeds are implanted directly into an organ, e.g., in the treatment of early-stage prostate cancer. Brachytherapy is often used in conjunction with external beam, usually to increase the total dose to a smaller volume at the site of greatest risk of recurrence, for example, in the postoperative management of cervical cancer.

Following the work done by Marie Curie and others, radium needles were initially used, until the importance of radioprotection was realized. In the modern era, artificially produced radionuclides are used, most commonly those derived from cesium (^{137}Cs), iridium (^{192}Ir), iodine (^{131}I), palladium (^{103}Pd), and gold (^{198}Au). The activity of these radionuclides is still calculated relative to that of radium. To protect health professionals and the patient, the process of using high-energy sources, such as ^{137}Cs and ^{192}Ir , has evolved considerably, most notably with the use of after-loading. Empty cylinders (for intracavity) or catheters and trocars (for interstitial brachytherapy) are inserted, and loaded with inert metal “dummy” sources that are visualized on radiologic imaging; this is done to verify the position and calculate the dose distribution. The patient is treated in a shielded room, either as an inpatient over several days, or in an outpatient brachytherapy suite, for shorter high dose rate treatments.

The radioactive sources are housed in a shielded safe in a remote-controlled after-loading unit, which looks very much like a small heating furnace. After a final verification of positioning, the applicator, catheters, cylinders, or trocars are connected with tubes to the after-loading unit. After all personnel have left the room, the active sources, which look like small beads, are remotely loaded through a pressurized system. The unit is programmed to control the position of the sources and the duration of the sources in any position to achieve the prescribed dose in a homogeneous fashion over the three-dimensional dose distribution. The unit can be paused, and the active sources retract temporarily into the safe within the after-loading unit, making it possible for personnel to enter the room to provide care.

Low-energy radionuclides such as ^{131}I , ^{103}Pd , and ^{198}Au do not pose the same concerns for radioprotection, and thus are used as permanent implants in the form of seeds, most commonly for prostate cancer.

Physics

An explanation of RT techniques and dosimetry requires a basic understanding of physics. The photons generated by the linac are very high-energy X-rays that do not have any charged particles in them. When a photon beam enters the body, it uses the Compton process to deposit energy. This means that it interacts with tissue by colliding with an atom’s loosely bound outer shell electron (Fig. 26.3). The photon continues along its path, but the electron is knocked off, like a billiard ball, at an angle that depends on the speed and angle with which it was hit. The electron travels (scatters) a distance that is proportional to the energy with which it was hit, meaning that higher photon energies propel electrons more in a forward direction than lower energies can do, before the electron is deposited, and the dose absorbed into the tissues. This triggers downstream free radical interactions, and these can cause DNA single-strand or double-strand breaks, or other injuries, including damage to base pairs and protein cross-links. The chromosomal aberrations that result from double-strand breaks mean that the cancerous cell cannot repair or duplicate at the end of its life cycle, leading to the principal cause of cell death.

If all of these electron energy deposits are added up, then a distribution curve showing absorbed dose and depth can be plotted (Fig. 26.4A) that shows that skin absorbed dose is less than 40%, and 100% or D_{max} occurs some distance into the skin at a depth that is consistent with the energy of the photon beam. The commonest energy used is 6MV, which has a D_{max} of 1.5 cm beyond skin. The dose then falls off at a steady rate

Fig. 26.3 Incident photon knocks an electron off the outer ring and scatters it along a pathway through a distance before the electron energy is absorbed.

Fig. 26.4 (A) Depth dose distribution for 6 MV photons: only approximately 30% of the dose is absorbed at the skin surface; the maximum dose (100%) is absorbed at a depth of 1.5 cm, and then attenuates by less than 5% per cm. (B) When two beams are opposed, depth doses can be added, resulting in an even distribution across the target volume. (C) If a higher dose is required at the skin surface, a strip of bolus material is placed on the skin.

that is just less than 5%/cm, meaning that 50% of the dose has been deposited approximately 11 cm into the body. If a tumor is situated centrally, this means that there is too much of a gradient of dose across it. To overcome this heterogeneity within the target volume, a second beam can enter the body

Fig. 26.5 Multileaf collimators (photographed looking into the head of the machine) are used to provide static shielding, or, when programmed dynamically, differential dose absorption for intensity-modulated radiation therapy.

(assuming a diameter of 20 cm) from the opposite side, again depositing its maximal energy at 1.5 cm, then attenuating at <5%/cm. The energy deposits from each side are added, a homogeneous distribution is achieved across the target volume (Fig. 26.4B), and the skin does not receive a therapeutic dose, unless bolus is used (Fig. 26.4C). The addition of right and left lateral beams (four-field box technique) would give an even tighter homogeneous distribution to the target volume, and, since the entrance and exit doses are shared between four beams, further skin dose reduction. This is the basis for using multiple fields, or beams, from different angles, to “focus” (a misleading term, since the beam does not focus on a spot, as light does through a lens) and deposit maximal dose to a target.

In conventional RT, most beams are delivered with uniform intensity across the field. Beam-modifying devices are accessories such as shielding blocks, wedges, and compensators, which are placed in the head of the machine to differentially absorb dose proportionally to the thickness of the device (i.e., more dose is absorbed through thicker regions, and less through thin), to improve dose homogeneity within the target. In modern linacs, blocking is done by a system of multileaf collimators (MLCs), which are narrow strips of metal in the head of the linac that act like miniblocks. Their shape can be programmed for shielding (Fig. 26.5). Three-dimensional conformal therapy uses multiple beams to be shaped in such a way that a significant amount of normal tissue can be excluded.

MLCs can also be programmed to move dynamically in and out of the beam, so that the amount of time in each position is adjusted to allow a variable amount of dose through each leaf, compensates for irregular shapes with great precision, and can control the dose to specified targets within a volume. This is the basis for intensity-modulated radiation therapy (IMRT), which involves identifying doses for individual or multiple target volumes and constraints for normal organs that need to be protected from the effect of radiation, and then using a sophisticated RT planning program that modulates the intensity across multiple individual beams or arcs with dynamic MLC, using an inverse planning system. This allows the creation of a very conformal plan that can even have convex and concave shapes to avoid a critical

structure, for example, avoiding the spinal cord in a way that conventional beams may not achieve (Fig. 26.6). It is also possible to “dose paint” so that different areas receive different doses at the same time, and also to reduce volumes, adapting to reduction in the tumor size. A similar result is obtained with tomotherapy, which uses principles of CT scanning to deliver intensity-modulated beams slice by slice. An advantage of IMRT over this system is that IMRT is delivered on a normal linac rather than a dedicated machine.

Image-guidance is essential for high precision in RT delivery (IGRT). Electronic portal imaging (digital MV or KV

Fig. 26.6 (A) Axial intensity-modulated radiation therapy plan of a sarcoma involving the mediastinum extending into a thoracic vertebral body. The technique allowed a radical dose (66 Gy) to be delivered to the target volume, but constrained the cord dose to a safe dose of 52 Gy. (B,C) Coronal and sagittal distributions.

X-rays taken on the RT machine) can take both orthogonal views of the target, e.g., anterior and lateral beams, and beam's eye view images. The utility of this is enhanced when there are recognizable and stable landmarks, for example, some part of the bony anatomy. However, when the target is mobile, then fiducial markers, such as gold seeds placed in the prostate gland or along the cervical os for brachytherapy, can serve as a surrogate for target location. The cone beam CT (CBCT) uses KV three-dimensional imaging to verify positioning for IGRT on the treatment couch.

Stereotactic techniques like radiosurgery deliver hypofractionated RT to small lesions in structures such as the brain. A linac-based process involves the use of multiple very small beams that cover a small target (2–5 cm) to a large dose of RT, delivering a therapeutically radical equivalent dose in just a few, or even just one, fraction. It has primarily been used on central nervous system tumors, including benign conditions such as arteriovenous malformations or schwannomas, immobilizing the head in a frame. Gamma knife uses a ^{60}Co source with similar principles. With the advent of IGRT, this principle is now applied to stereotactic body RT (SBRT) for sites elsewhere in the body, such as lung, liver, and paraspinal tumors. Large doses, for example 10–18 Gy, are higher depending on tumor size and location, are given 2–3 times weekly over fewer fractions than conventional fractionation to an ablative dose, but with much greater precision, and potentially less toxicity. It is well tolerated even by frail and ill patients.

Intraoperative RT (IORT) is used to treat small areas (3–10 cm) that are at high risk for recurrence immediately after the tumor has been resected, such as a retroperitoneal sarcoma, on the same day. An advantage of IORT is that critical structures, such as bowel, can be physically moved out of the beam's pathway. The radiation oncologist positions electron applicators (also known as cones) into the wound to cover the tissue at risk for microscopic residual disease that has been localized by the surgical oncologist (Fig. 26.7). The

Fig. 26.7 Intraoperative radiotherapy (IORT) delivering a large single fraction of XRT to the operative bed in the retroperitoneum. This photograph shows the cone, or electron applicator (the metal cylinder), after it has been positioned over the target volume. It will now be secured into place, the position verified, the monitor units and dose rate calculated, before personnel leave the room and XRT is delivered. Set-up takes approximately 15–20 minutes, but the treatment is delivered in only 2–3 minutes. (Courtesy, Edward Y Kim MD.)

cone position is stabilized and verified before being aligned with the head of the machine. Medical physicists calculate and verify the delivery. Personnel then leave the room, the beam is switched on, and the dose is delivered in less than 2 minutes. The cone is removed, and the surgeon closes up.

Radiobiology

Radiation injury can be viewed from two perspectives: the radiation effect on tumor cells, and the radiation toxicity on normal cells. The therapeutic ratio is a dose–response relationship between tumor control and normal tissue complications, and helps balance these two perspectives. In an ideal world, the curves representing tumor response and normal tissue complications would be well separated (Fig. 26.8A). Far too often, they are so close together that it is not possible to achieve a high enough dose to eradicate the tumor without causing harmful complications (Fig. 26.8B). Usually in clinical practice there is some degree of compromise, and traditionally, less than 5% risk of normal tissue complications is accepted (Fig. 26.8C), taking into account the specific risks of the situation.

Radiation toxicity is expressed during mitosis of normal cells. Acute toxicity occurs during treatment course or shortly afterwards. It is related to the total dose, the size of the volume irradiated, and radiosensitizing drugs such as chemotherapy. It occurs in cells with a rapid turnover, such as oral mucosa or skin epithelium, where cell division is necessary to maintain function. Even though these cells may be affected within a few days of starting fractionated treatment, their damage does not become manifest for at least 2 weeks as the progenitor stem cells do not have as rapid a turnover. Examples are skin erythema and desquamation, oral mucositis, and esophagitis. Even quite brisk reactions can heal fast once RT is completed (Figs. 26.9 & 26.10). Acute toxicity is reversible and does not predict for permanent damage. The exception is if there is consequential damage, i.e., there is persistent injury due to the destruction of the basement membrane zone with complete depletion of stem cells due to very high dose, and usually an additional factor such as chemotherapy, infection, or trauma. This can be found in chronic ulcers in the skin, bladder, or gastrointestinal tract. Delayed acute toxicity occurs 6 weeks to 6 months after the completion of treatment; it is also reversible. As with acute toxicity, it is dose-, volume-, and drug-related. Examples are radiation pneumonitis and Lhermitte's syndrome (a transient demyelination syndrome of the spinal cord, which does not predict for subsequent radiation myelitis).

Late toxicity occurs 6 months or later after the completion of RT. It represents damage that is expressed at the end of the life cycle of parenchymal cells that have slow cell renewal and a relative inability to repopulate from stem cells. It occurs in organs that have less dependence on cell turnover and have both proliferative and functional cell populations, primarily connective and nervous tissue. Examples are the endothelium of blood vessels, and osteoblasts and chondroblasts of bone. These injuries are characterized by fibrosis, often over many years, and are not reversible, thus of serious consequence. It is essential to factor these risks into dose limitations. They are strongly correlated with fraction size, and the type of radiation used (Fig. 26.11).

A method of quantifying the risk of permanent tissue damage is the concept of TD5/5, which is the total dose, given in standard fraction sizes, that produces a 5% risk of damage to a specified organ at 5 years.⁷ These figures have been updated to reflect modern conformal treatments⁸ and provide a working model based on pooled data to constrain the dose to an organ at risk during the treatment-planning process, as well as for guiding informed consent.

Ionizing radiation kills cells by damaging DNA either directly or indirectly. Direct action disrupts DNA, and can

Fig. 26.8 Therapeutic ratio curves. (A) In an ideal situation, a tumor response would be almost complete before causing any tissue reaction. (B) More commonly, the dose required to achieve adequate tumor response also causes an unacceptably high risk of normal tissue reaction. (C) An acceptable trade-off is one that allows adequate tumor control and less than 5% probability of normal tissue complications (NTC).

Fig. 26.9 Acute skin reactions can be severe, depending on multiple factors, including the volume and total dose. (A) Clinical photograph of the posterior thigh of a woman with a large (28 cm) sarcoma, treated with postoperative radiation to a total dose of 66 Gy. She had a history of over 240 lb (109 kg) intentional weight loss, and had marked skin redundancy, resulting in multiple folds, exacerbating her acute reaction. (B) Rapid improvement after just 7 days of conservative management with application of saline soaks. The white patches are healthy islands of new skin. (C) 14 days post completion of XRT.

cause lethal double-strand breaks. Indirectly ionizing radiation, which includes photons and neutrons, can cause damage by producing charged particles that then disrupt the DNA, but the damage is generally through indirect action, caused by the release of reactive oxygen species. Cell death can take several forms. Lethal chromosome damage can result in cellular death or loss of reproductive capacity. Apoptosis is a type of programmed cell death associated with activation of the tumor suppressor gene *p53* and is rapid, inducing no inflammatory response. Although it has been described in many different tissues, only certain tumors, such as

hematopoietic cells, primarily undergo apoptotic death. The commonest mechanism of cell death from radiation is through mitotic death when cells cannot divide because of damaged chromosomes. Another cellular response after radiation is senescence, in which cells survive and continue to function, but lose their capacity to reproduce and proliferate.

All organized tissues mount repair in response to injury. Radiation injury prompts the body to respond in a similar way as it does to other trauma, for example, surgery. However, there are three important differences. Firstly, radiation delivers a repetitive, daily injury during the course of fractionated

Fig. 26.10 Acute skin reaction in the neck. (A) An acute skin reaction at the base of the neck at a completion dose of 70 Gy. (B) 1 week later, again demonstrating rapid recovery and the skin islands. This reaction at the base of the neck is fairly typical, and is a result of the obliquity of the surface and narrowness of the shoulder.

Fig. 26.11 A severe late skin reaction as a result of fast neutron therapy 22 years earlier following excision of a large dermatofibrosarcoma protuberans (DFSP) tumor from the shoulder. It demonstrates characteristic telangiectasia, hypopigmentation, subcutaneous fibrosis and, medially, delayed healing of a minor skin abrasion.

treatment. Secondly, the injury caused by the release in the tissue of free radicals affects all cellular and extracellular components within the volume of tissue irradiated. Thirdly, radiation causes damage to the DNA.

Response to radiation injury causes a signal transduction pathway that is mediated by the ataxia telangiectasia mutated (ATM) gene to instigate DNA repair and to regulate cell cycle checkpoints, giving the cells additional time to repair. A cascade of cytokines is an immediate response, and may lead to both radiosensitization and protection.⁹ Interleukin-1 and 6, and tumor necrosis factor- α cause an inflammatory response and coagulation effect. Transforming growth factor- β (TGF- β) is one of the most widely studied radiation-induced cytokines, and plays multiple roles.¹⁰ It causes fibroblast differentiation as well as stimulating the production of collagen. It is involved in the synthesis and regulation of extracellular matrix molecules. Following radiation, the extracellular matrix is both quantitatively and qualitatively modified – degrading processes are altered and production of collagen synthesis increases. TGF- β also down-regulates thrombomodulin activity in endothelium, leading to platelet aggregation, and, from the platelets, release of more TGF- β , thus setting up a self-perpetuation production of TGF- β that contributes to the chronicity of radiation injury. However, it is primarily the sustained activity of TGF- β -driven myofibroblasts that causes the fibrotic reactions to radiation. Fibrosis is not an endpoint, but a dynamic process of fibroblast activity. In traumatic wounds, remodeling happens over years, but this capacity to remodel is lost in irradiated tissue and instead there is self-perpetuating reactive fibrosis. As a result, irradiated skin and soft tissue are susceptible to minimal trauma, creating a problem for surgical intervention. Radiation causes delayed

wound healing, with decreased wound-breaking strength because of the damage to the microvasculature and the decreased cellular elements.¹¹ These problems are related to the total dose, the dose per fraction, the timing of the surgery, and the extent of the surgery. The optimal time to operate on irradiated skin is the window provided once the acute reaction has resolved and before the development of excessive fibrosis, generally 3–10 weeks after completion of X-ray therapy (XRT).

Applications

Radiation treatment-planning and process

The preparation for radiation treatment, or planning, starts with a decision on the treatment intention – curative, palliative, or optimization of local control (complex palliation) – and the probable dose prescription. Following informed consent, the patient is simulated for the treatment. Simulation is the radiation oncologist's equivalent to the operative day, allowing dedicated time to accurately map out the areas for treatment. Two-dimensional planning with fluoroscopy has now been mostly replaced by a three-dimensional approach, using diagnostic-quality CT scan with contrast (intravenous and oral as necessary). The scanners are equipped with a flat, as opposed to concave, couch, and the bore is often extra-wide, to accommodate the proposed treatment position, such as arms above the head, or legs separated in a frog-leg position. To achieve a reproducible position, immobilization devices are made. The type of device depends very much on the treatment site. To treat the head and neck region, a mesh acrylic mask, similar to the type of mask worn by burn patients requiring compression treatment, is formed exactly to the patient's face and head with eye, nares, and mouth openings (Fig. 26.12). This not only allows reproducible positioning but also obviates the need for tattoos or other skin markings in visible areas. Extremities are immobilized using casts of the

Fig. 26.12 A mask to immobilize the head and neck in a reproducible position.

same material and body immobilization is achieved with the use of vacuum splints and bags. All of these devices are referenced to the couch position. Once the position is confirmed, immobilized, and referenced, the patient then has a CT scan in this position and goes home. These images are imported into a radiation treatment-planning system.

Using the original diagnostic scans, and often fusing them with the planning CT, the radiation oncologist starts delineating all the structures of interest on every CT slice as it is displayed on the workstation. Any visible tumor is delineated as one or several gross tumor volumes (GTV). These are then encompassed by one or more clinical target volumes (CTV), which include normal-looking tissue considered by the radiation oncologist to be at high risk of containing tumor cells. Defining this volume, and deciding on its dose, require judgment of risks and benefits, and are central to the discipline of radiation oncology. It is possible to have several CTVs that require different doses, depending on the likelihood of tumor burden. The CTV is then expanded to form a planning target volume (PTV) that accounts for measured movement of the tumor or organs, for example, to account for a lung mass moving with respiration, as well as other calculated variations.

The next step is to identify and contour all organs at risk (OAR), that is, those normal tissues that are sensitive to radiation – examples include kidneys, spinal cord, and femoral head. Each of these sensitive structures is identified with a dose constraint. The result is a three-dimensional digital representation of the patient, tumor, and organs at risk. Working with dosimetrists, a treatment technique is decided by placing multiple beams through a series of protocols to determine the optimal beam arrangement to cover the target volumes homogeneously to the prescribed dose while sparing critical structures. Dose volume histograms calculate constraints for the OAR, for example, in the thorax, the V_{20} refers to the percentage of cancer-free lung (i.e., without the CTV) that receives >20 Gy; if this is above 35%, it is strongly predictive for radiation pneumonitis. This aspect of radiation treatment planning, rather than just positioning the patient on the CT bed, is the heart of the simulation process.

Once the radiation treatment plan has been designed, it is checked by a physicist for quality assurance to ensure that the plan is technically feasible on the treatment unit, and that no further beam modification is necessary. The patient returns for a dry run of the plan, and verification of set up. During this session the patient is repositioned in the immobilization device on the treatment machine, and, using light beams, the geometric parameters are checked. Verification includes comparison of the portal imaging to the digitally reconstructed radiographs (DRR) from simulation to ensure that the isocenter of the fields, the field shapes, and the shielding are consistent with the plan. If all parameters set up correctly, the patient is tattooed to facilitate accurate placement on the machine on subsequent visits. If there are any problems, adjustments are made before the patient returns the next day for the start of actual treatment. Further verification is done with cone beam CT, and adjustments, or shifts, are made as necessary, and usually repeated on a daily basis. Image-guided radiation therapy (IGRT) thus verifies that highly conformal plans are delivered not only accurately, but also with

Clinical applications

Units of radiation

The unit of absorbed radiation dose is the gray (Gy), corresponding to 1 joule of energy per kilogram of tissue. One gray equals 100 cGy. SI units that are named after people are, by SI convention, lower case when the whole name is used, but capitalized when the abbreviation is used. The gray replaced the older unit rad. One rad is equivalent to 1 cGy.

Treatment intention and dosing

The dose is determined by the intention of the treatment. Radiation can be used as the primary modality of therapy or combined with surgery and chemotherapy. When the treatment intent is curative, radical doses, such as 66 Gy for early (and 70 Gy for late) laryngeal cancer or 80 Gy for prostate cancer, are delivered in standard fractionation sizes of 1.8–2.0 Gy per daily fraction, 5 days a week, over periods of 7 weeks or more. Typically, the maximum dose is applied to known tumor, but lower doses (45–50 cGy) are used to treat tissues that have the potential for microscopic disease, for example, the peritumoral edema around a soft tissue sarcoma. However, when resection margins are histologically positive, a higher dose is needed, e.g., to 70 Gy, and the context is no longer adjuvant.

In noncurative situations, treatment may be used to palliate symptoms such as pain or bleeding, employing hypofractionated regimens that use smaller total doses but a larger dose per fraction. A common palliative course would be 20 Gy delivered in 5 fractions of 4 Gy. However, there are also noncurative situations when a patient has known metastatic disease, but bulky or aggressive tumor at the primary site that is, or will shortly become, very symptomatic and impair quality of life. Radical radiation approaches are used to optimize local control, for example, an unresectable fungating breast cancer even in the presence of bone metastases.

Dose can also be hyperfractionated, when smaller fractions are given twice a day, so that treatment can be accelerated, potentially improving tumor cell kill and causing less repopulation of very fast-growing tumors. This can also be a way to protect normal structures from late irreversible toxicity, especially in high-risk situations like retreatment. Hypofractionated RT with a large dose per fraction, but fewer fractions, has traditionally been reserved for palliative RT, as described above. However, when the volume is small, the risk of late toxicity is low, and the high dose is ablative, treatment can be curative, as in SBRT, described earlier. It is also increasingly used in oligometastatic situations for patients with good performance status and a small burden of metastatic disease that is chemosensitive, as this approach can improve survival, and may have an abscopal effect.^{12,13}

Patient selection

As in any branch of medicine, careful patient selection and informed consent are essential. Patients are often referred to radiation oncology when surgery or chemotherapy options are not feasible because of comorbidities or poor performance status. There are some basic principles to follow. For all patients, but particularly for young people, potential benefit of radiation must be weighed against the late sequelae of

radiation, including the risk of second malignancy. Poor performance status and patient preferences can shift a potentially curative scenario into one of observation, or nonradical radiotherapy. However, chromosomal fragility syndromes such as Li–Fraumeni syndrome and Rb or ATM gene carriers are contraindications to radical or curative RT. Previous RT is only a relative contraindication, in that it may be possible to give a palliative dose, or even to treat to radical doses using stereotactic techniques to treat small volumes.

Hints and tips

- For all patients, but particularly for young people, potential benefit of radiation must be weighed against the late sequelae of radiation, including the risk of second malignancy.
- Chromosomal fragility syndromes such as Li–Fraumeni syndrome, and Rb or ATM gene carriers, are contraindications to radical or curative radiation therapy.
- Previous radiation therapy is a relative contraindication.

Breast cancer

Until 1997, it was widely believed that XRT for breast cancer only offered local control, and that any improvement in survival was related to the effect of adjuvant systemic therapy. Any survival advantage of radiation was negated by deaths that may have been caused by cardiotoxicity from large fractions and older, less precise techniques. Two landmark studies examining the role of RT in node-positive breast cancer demonstrated significantly improved survival with RT and changed breast cancer practice dramatically.^{14–16} The impact on overall survival has been confirmed in subsequent meta-analyses.^{17,18} Although not as dramatic a finding as for nodal XRT, radiation to the intact breast alone also confers a small survival advantage.¹⁹

Breast conservation

Adjuvant breast irradiation allows breast conservation by reducing the risk of breast cancer recurrence. The evidence for the effectiveness of postlumpectomy radiation is strong, and derived from many randomized clinical trials,²⁰ and provides equivalent²¹ or even improved²² survival for younger women in modern series. It is one of the commonest radiotherapy treatments in RT practice. Cosmesis was also found to be satisfactory in a large European study that used rigorous assessment methods.²³ It is contraindicated when there has been previous radiation treatment to the breast or chest wall (e.g., in the treatment of Hodgkin's lymphoma), during pregnancy, or when the margins are positive. Women with active connective tissue disease, especially scleroderma,²⁴ may have an increased risk of acute and late toxicities, and woman with large tumors may have poorer cosmesis as a result of a larger defect. These, however, are only relative contraindications.

Indications for postmastectomy radiation (PMRT)

PMRT is indicated for circumstances where the tumor is 5 cm or larger; when the margins are positive, or closer than 1 mm; or where there are regional lymph node metastases, since these

are all strong predictors of chest wall recurrence. Radiation should also be considered when the lymph node status is uncertain, and the histology shows that the tumor has evidence of lymphovascular involvement, which predicts for local recurrence.^{25,26} Conversely, it is not indicated when the tumor size is less than 5 cm with negative margins and without spread to the lymph nodes. There is even evidence to suggest that tumors of 5 cm that are N0 do not benefit from PMRT.²⁷

Radiation of the nodal draining areas

Nodal irradiation is indicated when four or more lymph nodes are positive; RT for 1–3 nodes is still a gray area, even though it has become fairly routine practice. When there has been an adequate sampling, the upper axilla is usually not included in the volume, although the supraclavicular area, i.e., the next echelon of nodes, is included. Internal mammary (IM) nodal RT is controversial, and subject to institutional bias.²⁸ IM nodal involvement is known to be more common in medial and central breast cancers, and to be present when axillary lymph nodes are positive,²⁹ although IM clinical failure is rare. Positive IM nodes detected on imaging such as positron emission tomography (PET) fludeoxyglucose scan are rarely resectable, unlike axillary nodes, and thus need a higher dose of RT,³⁰ as this situation is no longer one of adjuvant therapy.

RT techniques

The target volume includes the breast, subcutaneous tissues, and chest wall. In any technique used to cover these tissues, the lower axilla is usually within the high dose volume. The classic technique is breast “tangents”, using medial and lateral beams (Fig. 26.13) that are either angled or blocked to reduce the dose to the heart and lungs. The beam can be modified

Fig. 26.13 Conserved breast treated with classic breast tangents, internal mammary chain (IMC) not covered.

with a wedge-shaped device to reduce the “hot spot” of radiation dose that can result from this technique. IMRT and other conformal approaches are frequently used now, obviating the need for wedges, providing homogeneous dose distribution and reducing treatment time.

The same techniques are used to treat the chest wall, although the scar and drains have traditionally been in the high-dose volume, necessitating bolus to ensure that the scar receives an adequate dose (Fig. 26.14). The use of bolus on the entire chest wall is debatable, except in the case of inflammatory breast cancer, where tumor cells, by definition, invade the dermis, and so it is essential to achieve full dose on the chest wall skin.

Fig. 26.14 Post mastectomy XRT plan. (A) Including the IMC nodal area using a wide tangent technique, resulting in a larger volume of irradiated lung. (B) The use of bolus to bring the surface dose to 100%, and losing the skin sparing effect.

Apart from the lower axilla, which is incidentally covered in breast or chest wall techniques, additional planning is required to ensure that the targeted lymph node areas match carefully to the breast/chest wall volumes to avoid overlap and increased toxicity to the normal tissues, including the brachial plexus. The small apex of the ipsilateral lung receives a full dose when treating the supraclavicular lymph node. If overlap of fields happens, a portion of the brachial plexus may receive almost a double dose of radiation, and thus be at very high risk of brachial plexopathy. If treating the IM nodal chains, there are two main techniques: the first uses an extra-wide tangent arrangement, which can result in a significantly larger volume of lung tissue being damaged. The addition of an electron field patched on to the medial aspect of the tangent fields delivers a fairly homogeneous dose over the IM nodes, despite increasing lung and also cardiac dose, if the tumor is located on the left side. Getting adequate dosing into the IM nodes, and avoiding critical structures, can be especially challenging when an expander has already been placed in the chest wall prior to using this technique (Fig. 26.15), sometimes causing the electron dose to “splash” on to the contralateral breast. This does not happen often on the flat chest wall of PMRT, or when the breasts are natural and fall to the side, leaving the ipsilateral parasternal area flat.

The standard adjuvant dose to the chest wall or breast ranges from 45 to 60 Gy, given in 1.8–2 Gy/fraction, depending on practice, with the same dose used for the nodal areas. As a result of a Canadian study in early-stage breast cancer, hypofractionated RT prescribing 42.5 Gy at 2.66 Gy/fraction provides the same local control as more prolonged treatment schedules. Despite the larger dose per fraction, cosmesis remains acceptable on long-term follow-up.^{31,32}

Even in the absence of positive margins, local recurrence is most likely to occur in the operative bed, or tumor cavity. The use of a boost to this volume can reduce this risk, and is recommended in patients at higher risk for local failure (age <50 years, positive axillary nodes, lymphovascular invasion, or close margins). A European study³³ showed that women aged 40 or younger benefited significantly from extra treatment to the tumor cavity, halving their risk of local recurrence from 19.5% to 10.2%. The benefit was less striking in women aged over 40. Boost doses of 2 Gy/fraction usually bring the total dose to the tumor cavity to a minimum of 60 Gy, and can be delivered with photons, including using conformal or IMRT techniques, electrons, a combination of photons and electrons, brachytherapy, or, more recently, with protons. The technique again depends on institutional experience and operator skill. Addition of a boost can result in fibrosis and compromise cosmesis.³³

Another approach has been to treat only the area most at risk, i.e., the cavity plus a margin, and not treat the whole breast. Accelerated partial breast irradiation seems to provide equivalent local control in patients over age 60 years, with low risk features, in a very convenient fashion with 10 b.i.d. treatments of either brachytherapy (total 34 Gy) or external-beam photon therapy (total 38.5 Gy) to the tumor bed.

Head and neck cancer

Head and neck cancers are mostly squamous cell carcinomas (HNSCCs). Radiation has an important role in the primary, postoperative, and palliative aspect of their management.

Fig. 26.15 (A) Treating a right breast mound with inflated expander in place can mean that the medial aspect of the contralateral breast may be “splashed”. (B) The expander *in situ* is more problematic for the contralateral breast when the IMC lymph nodes are treated.

Previously, a general principle of minimizing toxicity by using either surgery or radiation, and keeping the other modality for salvage, was preferred. However, increasingly, especially in locally advanced disease, combined modality, particularly postoperative radiation treatment, is used because it has been shown to reduce the incidence of recurrence, especially in the cervical lymph nodes. The use of concurrent chemotherapy has also changed the practice over the last 10–15 years. Several studies have shown a benefit in both survival and local control,³⁴ as a result, platinum-based therapy has become the standard of care in the management of all but the most favorable – early disease that has a high cure rate with RT alone. However acute toxicity is considerably worsened by concurrent chemotherapy, and some patients are not optimal candidates for cisplatin due to competing comorbidities or poor performance status. In RTOG 9501,³⁵ cetuximab concurrently with radiotherapy for locally advanced head and neck squamous cell carcinomas showed an improvement in survival and local control compared to radiation alone and appeared to have less toxicity compared to cisplatin based on historical trials.

The incidence of HPV-associated oropharyngeal cancers has been increasing, with a decrease in rates in smokers. HPV-associated oropharyngeal SCC clinically behaves differently with a better prognosis. De-intensification of therapy for HPV-positive tumors is being investigated in multiple ongoing trials with the overall goal to reduce morbidity in HPV-related HNSCC without a detriment in survival and local control. Data from these studies will help guide optimal treatment in this patient population.

SCC head and neck cancers have lower local control rates if treatment time is extended, due to repopulation of tumor cells.³⁶ In order to overcome this effect, efforts have to be made to deliver five fractions per week even if it requires treating twice a day to do so. Approaches that intensify the course of treatment by giving it over a shorter period of time (accelerated fractionation) or giving treatment more than once a day using

a smaller dose per fraction over the same time period (hyperfractionation) can improve outcome but result in severe acute toxicity so that breaks in treatment may be necessary, thus negating the benefit of altering the fractionation schedule.

Doses used for gross tumor are in the 66–72 Gy range. Subclinical disease is treated to 50–60 Gy. Before the introduction of IMRT, these areas were usually treated sequentially, covering the larger volume to a “microscopic” dose, before boosting the smaller volume or volumes containing gross disease, although a concomitant boost was sometimes used. However, IMRT allows a technique of “dose painting” or differential dosing so that the areas at higher risk are programmed to receive a slightly higher dose per day than the areas of low risk. It can also reduce the dose to the parotid, reducing the risk of permanent xerostomia.³⁷ Submandibular gland-sparing IMRT has also been utilized in select patients to reduce xerostomia with excellent locoregional control.³⁸

Acute toxicities occur during the course of treatment and resolve 2–3 months following completion of treatment. They are reversible unless the acute damage is confluent, causing damage to the basal membrane and depleting the supply of stem cells. Mucositis, which is exacerbated by smoking and alcohol, starts during weeks 2–3, becoming confluent by the end. It affects the mucous membranes within the high-dose volume and results in difficulty in swallowing. Because of concerns about nutritional status, percutaneous endoscopic gastrostomy tubes are inserted before the start of treatment. Mucositis is painful and mouthwashes containing local anesthetic help this, but usually narcotics are also required. The skin develops erythema by weeks 3–4, even with the aggressive use of topical aloe vera gels, other unguents, and steroids. Reaction is inevitably brisk with moist desquamation by completion of treatment. Because of dose to the parotid, patients will also experience change in taste; radiation causes xerostomia, changing the consistency of saliva by drying the water component, which results in thick mucoid secretions

that are difficult to clear. During treatment patients often lose weight and experience fatigue.

Late toxicities depend on the size of dose per fraction given. They occur 6 months to 3 years following the completion of treatment and unfortunately are permanent and progressive. The primary problem is fibrosis that can affect the subcutaneous tissues, musculature, and joints. The patient can experience trismus, neck stiffness, aching, and swallowing difficulties as a result. If the parotid has been treated to more than 26 Gy the patient may be left with permanent xerostomia, which can exacerbate dental problems. The patient may also experience voice changes due to chronic laryngeal edema and/or cartilage damage. Patients are also at risk of osteoradionecrosis (ORN), as described later.

Soft-tissue sarcoma

Sarcomas comprise a heterogeneous group of more than 100 bone and soft-tissue mesenchymal subtypes. Soft-tissue sarcomas (STS) are rare mesenchymal malignancies arising from connective tissue. They can arise anywhere in the body but most commonly affect the extremities and trunk. In the pediatric population, 7% of tumors are STS,³⁹ with half of these being rhabdomyosarcoma, and, especially in younger children, these tumors are more responsive to chemotherapy, so radiation is either spared or used at lower doses to avoid arresting growth or increasing the risk of a second malignancy.

Because of the rarity of STS (only about 10 000 are diagnosed per year in the US) and the numerous locations and subtypes, they are best managed in specialized multidisciplinary groups that include dedicated sarcoma radiation oncologists. Prognosis depends on size, grade, histological subtype, and superficiality of the tumor. Location is also important; retroperitoneal sarcomas have an independently worse outcome, but usually do not present until tumors are very large.

Although the primary treatment of STS is surgery, adjuvant radiation is important for limb and function conservation in extremity sarcoma and reducing the risk of local recurrence. Overall, local control rates are approximately 80% at 5 years.⁴⁰ If the patient is unfit for surgery, primary RT can provide useful local control. The role of XRT in adjuvant treatment of osteosarcoma, chondrosarcoma, and chordoma is minimal, although it can be a useful modality for palliation.

Doses and techniques in adults

Postoperative adjuvant XRT is indicated after resection of high-grade or large tumors with negative margins, or any tumor with positive margins.

Standard adjuvant postoperative radiation doses for STS are 60–66 Gy in 30–33 fractions, or higher if any gross disease remains, with reduction in the size of the volume after 50 Gy. The CTV is often large, encompassing the entire operative bed, which is determined with postoperative magnetic resonance imaging (MRI) to visualize the operative “footprint”, or by reconstructing preoperative imaging (e.g., fusing with diagnostic MR scan) and using surgical clips, operating room report, and guidance from the surgeon to determine the extent of the target volume. Generous margins are used to cover any uncertainty.

The standard preoperative neoadjuvant XRT dose is 50 Gy given in 25 fractions of 2 Gy over 5 weeks. The GTV covers

the radiologically visible tumor and the CTV covers peritumoral edema as seen on MRI T2 imaging, or CT or PET CT volume plus 2–3 cm. If the margins are positive after resection, a further 16 Gy is usually given, although this practice may not be necessary.⁴¹

Optimal immobilization is important in the RT planning process. It is also necessary to delineate bones, joints, and perineum so that dose to these sites can be minimized. It is also necessary to spare a longitudinal strip of skin and subcutaneous tissue so that lymphatic drainage remains intact to reduce the risk of chronic lymphedema. Conformal techniques, including IMRT, are often needed to meet these constraints.

The issue of whether pre- or postoperative XRT is used remains controversial. Certainly the preoperative advantages of an early start of XRT, a smaller irradiated volume and likely lower dose, and, as a result of these features, less fibrosis and better functional outcome⁴² are compelling. However, the delay to definitive surgical treatment and the doubling of risk of wound complications (17–35% in the Canadian randomized trial) are also serious issues to consider.⁴²

Skin cancers

Nonmelanoma skin cancers

This group encompasses basal cell carcinoma (BCC), SCC, Merkel cell carcinoma, and cutaneous angiosarcoma. Of these, the commonest are BCC and SCC. The majority are radiation-related, albeit mostly solar radiation! Due to their chronic immunosuppression, patients who have undergone transplantation are more likely to develop SCC, which tends to behave more aggressively. Primary radiation is indicated when the patient is not a surgical candidate (due to comorbidities, anticoagulation, or patient preference) or when surgery may risk function or cosmesis, and in the adjuvant setting to reduce the risk of local recurrence. It can provide good palliation for locally advanced unresectable disease, often with high doses to optimize local control. Decisions about the extent of the RT target volume are based on the risk of lymph node metastases, and inclusion of the regional nodes in high-risk disease. An important consideration is the presence of perineural invasion, which may involve treating extended volumes along neural pathways. In all, 30–40% of incompletely incised BCCs recur but they can be salvaged equally with surgery or radiation.⁴³ Doses for the primary treatment of BCC are in the range of 40–50 Gy delivered in 10–20 fractions, but higher doses are needed for SCC, similar to those for head and neck squamous cell cancers. Small lesions without risk for nodal or perineural involvement can be treated with hypofractionation.

When delivering radiotherapy for skin cancers one has to be able to achieve a high dose superficially. One of the best ways to do this is to use superficial kV equipment that provides 100% of the dose at the surface and a very tight penumbra resulting in smaller fields. However, this equipment has now been largely supplanted by electrons, which have a larger penumbra due to their propensity to scatter. Furthermore, low-energy electrons do not provide 100% of the dose at the surface, which is corrected with the use of bolus.

Although treatment with XRT is highly curative, late toxicities of treatment result in cosmetic changes related to change

in pigmentation, fatty necrosis, subcutaneous fibrosis, and dermal telangiectasia. These tend not to arise for 2 years or more after treatment and not all patients suffer these effects. These risks are increased with larger volumes and larger fraction size. Fortunately, since many of these cancers are small, and the patient population is, by and large, elderly and frail, one can still get away with using hypofractionated treatment over a shorter period of time.

Merkel cell carcinoma is a rare neuroendocrine skin tumor that has a lethal potential for spread. Both the local disease and the regional lymph nodes need to be treated. Inclusion of nodal areas means that radiotherapy volumes become larger and smaller fraction sizes are necessary. However, hypofractionation with single fraction has been shown to provide excellent control with possible abscopal effects.⁴⁴

Angiosarcoma is primarily treated with surgery. When this is not possible or when there is recurrence or presence of positive margins, radiation is necessary with higher doses between 66 and 70 Gy. Tumor location can be an important issue in planning treatment. Treating the entire scalp but avoiding the brain requires sophisticated treatment planning. One technique is called the "German helmet", in which a combination of photons and electrons is used to minimize penetration to the brain and subsequent cognitive dysfunction.

Malignant melanoma is generally thought to be relatively radioresistant. *In vivo* studies show that the cell survival curve has a very broad shoulder, indicating that these cells have a large capacity to repair sublethal damage. The way to overcome this is to hypofractionate with large doses per fraction. Adjuvant radiation can reduce the risk of local recurrence in high-risk adjuvant situations. At the MD Anderson Cancer Center, criteria for this include desmoplastic histology, depth >4 mm with ulceration or satellite lesions, positive margins, or recurrent disease.⁴⁵ Radiation to involved or high-risk but clinically negative lymph nodes can improve control. Hypofractionated radiotherapy is effective, 6 Gy twice a week for a total of 30–36 Gy regimens such as are commonly used,⁴⁶ albeit with a higher risk of lymphedema, improving local control from 50% to 87%⁴⁷ without affecting survival. Radiation also plays a major role in palliation of brain and bone metastases, and uncontrolled tumor.

Benign disorders

RT was historically used to treat many benign conditions, such as ankylosing spondylitis, tinea capita, and eczema, that fortunately now are treated with other therapies. However, it is still used in the treatment of noncancerous conditions such as prevention of heterotopic ossification after hip replacement surgery and keloid scars.⁴⁸ Doses used are low, so unlikely to cause significant problems with fibrosis. However, especially in a younger person, the concerns about development of a radiation-induced malignancy must be weighed against the potential gain of using radiation for benign disease.

Specific toxicities and complications

Bony injury

ORN is a necrotic wound manifested in irradiated bone that persists without healing for 3–6 months, in the absence of

tumor recurrence.⁴⁹ It presents as clinically exposed bone, sometimes without any pain, and radiologic evidence of necrosis on both CT and MRI between 1 and 3 years following radiation. Radiologic findings may mimic disease recurrence. ORN is mostly seen as a result of treating head and neck cancer and most frequently affects the mandible. Radiation-related risk factors include fraction size (>200 cGy), the volume of bone irradiated, a total dose to the bone of >6000 cGy, and re-irradiation. The modality of radiation used is also important, because particle therapy (electrons, neutrons, and protons), brachytherapy, and kilovoltage energy can result in higher absorbed doses within bone than from megavoltage XRT, e.g., photons. The use of three-dimensional treatment-planning systems, improvements in immobilization, as well as conformal techniques such as IMRT and higher precision with IGRT for localization, help to minimize the volume of bone in the target, as well as the dose. Other risk factors in the head and neck region include poor oral hygiene and dental extraction, making careful dental preparation an integral part of treatment planning. Prior to initiation of radiation therapy, patients undergo dental clearance. Dental extractions, if indicated, are done prior to the start of RT. During RT planning, the radiation oncologist delineates the mandible, maxilla, and salivary glands and identifies dose constraints. After completion of radiotherapy, patients proceed with life-long daily fluoride treatments and maintain a pristine dental hygiene regimen. Concurrent chemotherapy causes mucositis and xerostomia, further increasing the risk, as does the xerostomia resulting from relatively low doses to the parotid. ORN arising in other sites can also be associated with trauma and surgery.

Although ORN in the head and neck region had an incidence of 6.8% in 1968,⁵⁰ it is fortunately now quite rare, with recent series reporting incidences of 0–2%.^{51,52} Bisphosphonates can cause osteonecrosis without radiation,⁵³ but it is still unclear what increased risks are incurred with concurrent radiation and bisphosphonate therapies.

Bone fractures occurring within the irradiated volume are more common. Rib fractures tend to be the result of coughing. Limb fractures can happen with minimal trauma. No intervention is necessary for clavicles or ribs, but long bones usually require an intramedullary nail and there can be long delays in union. An analysis of fractures associated with soft-tissue sarcoma identified that the total dose to the bone and the volume irradiated were critical factors, leading to recommendations that the maximum dose to the bone should be 5900 cGy, and that the volume of bone receiving >4000 cGy be limited to 64%.⁵⁴

Bone growth in children

Prior to the development of effective chemotherapies, radiotherapy was the main modality in the treatment of pediatric tumors, so it was widely recognized early on that radiation impedes bone development in children, leading to limb shortening, asymmetry (including scoliosis), deformity and functional impairment. It was difficult initially to quantify dose constraints as treatments and dosimetry were very heterogeneous. Radiologically, there are changes on the growth plate that resemble rickets, with metaphyseal sclerosis, metaphyseal fraying, and epiphyseal plate widening, reflecting the radiosensitivity of rapidly proliferating cells in this region.

The child's age at the time of radiation is important, since most bone growth occurs in the first 5 years. The most important radiotherapy factors are the total dose and volume of bone irradiated. Although 30 Gy is considered the tolerance threshold dose, growth effects are seen with as low a dose as 15 Gy, suggesting a very steep dose–response curve in this range.⁵⁵ If the spine is within the high-dose volume, uniform dose across the whole vertebral body is recommended to reduce the risk of scoliosis.³⁹

Craniofacial growth is different to long bones, since these bones develop through intramembranous ossification, resulting in a complex three-dimensional pattern of growth.⁵⁶ Disruption of this growth by radiation in all or any part of the head and face can cause significant clinical problems, including distorted appearance and functional problems related to eating. Dentition is also affected.

Cranial irradiation is used for prophylaxis against central nervous system relapse in leukemia. Not only can this affect cognition and bone growth, it can also impair the production of growth hormone, which results in decreased bone mineralization.⁵⁷ Genetic factors are important, for example, in the treatment of retinoblastoma, where there may be much greater sensitivity to XRT. Biological factors that are disrupted by XRT include remodeling of the extracellular matrix in response to paracrine and endocrine signaling that affects chondrocyte production. Radioprotective agents, such as amifostine, have been studied *in vivo* and found to protect a number of cell lines, such as osteoblast-like, endothelial, and fibroblastic, from harmful effects of radiation.⁵⁸

Cardiovascular disease

There has been a well-established correlation between radiation and risk of cardiac morbidity and mortality, particularly associated with treatment of breast cancer and Hodgkin's lymphoma. Radiation therapy for left-sided breast tumors increases risk of subsequent ischemic cardiac disease by 7.4% per Gy mean heart dose that follows a linear, no-threshold relationship.⁵⁹ Several techniques have been developed to reduce heart and coronary vessel dose. Deep inspiratory breath hold (DIBH) is a technique to reduce the heart dose for left-sided breast cancer irradiation, with current data showing clinical benefit based on modeled risk estimates, most notably in patients with high baseline cardiac risk.⁶⁰ This technique displaces the heart away from the chest wall (Fig. 26.16). CT simulation involves both DIBH and free breathing scans for dosimetric comparisons of the heart and chest wall separation with breath hold technique.

Lymphedema

The mechanics of RT-related lymphedema are due to the radiation-induced fibrosis causing compression of the lymph vessels. When assessing lymphedema in someone who has had a previous cancer diagnosis, it is important to exclude recurrent disease before assuming that the edema is related to treatment. However, lymphedema after breast cancer is common. Norman *et al.* identified 42% 5-year accumulative incidence in a 5-year prospective, population-based study of breast cancer survivors. However, the majority (23%) described only mild lymphedema, and only 2% had developed chronic, severe edema.⁶¹

Independent risk factors for breast cancer-associated lymphedema include radiation treatment of the axilla, the extent of axillary lymph node dissection, the type of breast surgery, and the presence of regional lymph node metastases.⁶² A history of infection and injuries, and the patient's body mass index are also associated factors. The combination of XRT and axillary lymph node dissection confers the greatest risk.⁶¹ A large series from Massachusetts General Hospital reported lymphedema rates of 10% in women who had breast-conserving surgery and XRT to the axilla,⁶² although historically, higher rates have been reported. It has also been suggested⁵⁸ that, with survival and longevity, this late toxicity becomes more prevalent. However, as sentinel lymph node dissection has become the standard of care in early breast cancer, this will result in a lower risk of lymphedema than conventional axillary lymph node dissection risks.⁶³ ACOSOG Z0011 demonstrated that complete axillary lymph node dissection could be omitted in select patients with limited sentinel node-positive disease. This trial compared sentinel lymph node resection with versus without axillary lymph node dissection in patients with T1–2 tumors with up to 3 positive sentinel lymph nodes. All of the patients underwent

Fig. 26.16 Reducing dose to the heart in left-sided breast tumors. (A) Radiation treatment CT simulation for whole-breast irradiation with deep inspiratory breath-hold technique avoids the heart and coronary arteries in comparison to using standard free breathing (B). (Courtesy, L. Christine Fang MD.)

breast-conserving surgery with whole breast irradiation. The study required no dedicated axillary lymph node irradiation. There was no difference in local or regional recurrence, supporting omission of axillary lymph node dissection in this population.⁶⁴ Initial results of the AMAROS trial (which randomized patients with a positive sentinel lymph node to ALND or axillary RT) show excellent 5-year local control and survival with less lymphedema in the radiotherapy arm.⁶⁵

Brachial plexopathy

Brachial plexopathy is most commonly due to metastatic disease involving the brachial plexus, and it can be very difficult to distinguish between the late side effect of XRT versus recurrence. PET has been reported to be helpful.⁶⁶ However, it is also a rare (1%) complication of radiation treatment.⁶⁷ Its development is dependent not just on total dose, with a marked increase above 6000 cGy, but also on the dose per fraction. RT technique is also a very important factor, as older breast RT techniques that extended to the lymph nodes could result in overlapping fields just above the clavicle immediately above the brachial plexus, meaning that the plexus received up to twice the prescribed dose. Concurrent chemotherapy also increased the risk.

Radiation-induced malignancies

Radiation has been shown to induce malignant transformation *in vitro*, for example, in laboratory mice, and *in vivo*, for example, from atom bomb survivors, as well as long-term follow-up studies. Three mechanisms for radiation-induced malignancy have been suggested: (1) DNA damage and subsequent mutation; (2) disturbances of multiple defense or control mechanisms within the cell at the molecular level; and (3) the chronic ongoing damage of irradiated tissue.⁶⁸

Radiation-induced malignancies are rare within the first 5 years after treatment, and usually present many years after treatment. As more cancers are cured, and the number of long-term survivors increases, so does the risk of radiation-induced malignancies.⁶⁹ Although a second malignancy rate of 1 per 100 000 patients treated is often cited, this figure is only an estimate, and may be misleading. Many different mathematical models are used to standardize the doses, dose per fraction and quality of radiation, as well as the volume of the target, the organs treated, and the age of the patient. Second primary tumors are more common in those who have already had a malignancy, with a RR of 1.12, regardless of treatment. Chemotherapy, especially alkylating agents, is also carcinogenic, although more likely to induce leukemia than a solid tumor, and within a much shorter latency period. The addition of chemotherapy during RT also increases the risk. Some of the best data come from follow-up of childhood survivors,⁷⁰ although also identifying large variations in findings. In children, susceptibility varies according to age and the type of tissue irradiated, with leukemia developing after 5–8 years, and solid tumors, the commonest of which are thyroid cancers, breast cancers, and bone and central nervous system malignancies, usually occurring many years later.^{71,72} Some second primary malignancies, especially carcinomas, arise around the periphery of the high-dose volume. Concerns have been expressed about the risk of techniques such as IMRT: although they have very conformal high-dose

volumes and can minimize dose to critical structures, there is a large lower-dose volume from the multiple-beam entry through normal tissues.^{71,73} Thyroid cancer is unlikely when the gland has received doses over 30 Gy. Conversely, sarcomas tend to arise in heavily irradiated tissues, and appear to have a dose–response effect. Survivors of Hodgkin's disease treated with mantle radiation (i.e., mediastinal, cervical, and axillary nodal XRT with shields over the lungs) have four times the risk of developing breast cancer. The woman's age at the time of XRT is extremely important: adolescent girls aged 10–16 years have a 136-fold greater risk of developing breast cancer than their nonirradiated peers.⁷⁴ Factors such as smoking can markedly increase the risk of developing primary lung cancer, even in parts of the lung that received only a tiny scattered dose. Some genetic predispositions, such as Li–Fraumeni syndrome, which is linked to germline mutations of the p53 suppressor gene, or ATM and RB gene carriers, are exquisitely susceptible to any form of radiation.

Exposure to radiation

Radiation accident studies have shown that there is a proportional relationship between the amount of radiation exposure and the risk of developing cancer.⁷⁵ The sievert (Sv) is the SI unit that measures the biological effect of absorbed dose, taking into consideration the relative biological effectiveness of the radiation (e.g., 1 for photons and electrons, 20 for high-dose neutrons and α -particles) and the biological effect on different organs. When all of these weightings are 1, then 1 Sv = 1 Gy. The gray is a unit of absorbed dose in any material defined only by physical, not biological, properties of radiation. The sievert is used to quantify risk of radiation damage, including cancer. To put this into perspective, on average, a chest X-ray is 0.34 mSv, mammogram 0.48 mSv, and CT thorax 6 mSv. The biggest contributor of background radiation source is radon, which is approximately 2 mSv annually. There is background cosmic radiation of 0.24 mSv per year, and a passenger on a return flight between Seattle, WA and Toronto, ON would be exposed to 0.085 mSv. Radiation oncologists are limited to an occupational exposure of 50 mSv per year, excluding medical and background sources of radiation, but after the March 2011 earthquake and subsequent explosion in a nuclear reactor, the emergency nuclear workers at Fukushima, Japan were exposed to up to 400 mSv per hour. The Japanese public already has a 20–25% lifetime risk of cancer, and exposure to 400 mSv increases that risk by 2–4%. Survivors of the atom bombs in Hiroshima and Nagasaki have an excess risk of cancer (RR 1.42 at 1 Sv) that persists through their lifetime. Exposure to 1 Sv increases the lifetime risk of fatal cancer by approximately 5%. The most sensitive organs to this sort of accidental exposure are bone marrow and thyroid, and leukemia is the most common resulting malignancy. Radiation sickness is an acute effect of radiation exposure, causing nausea, headache, and bone marrow suppression, and is rarely experienced at exposures of less than 1 Sv.

Regardless of the regulatory safety requirements, the ALARA (As Low As Reasonably Achievable) principle is the mantra of all who work with ionizing radiation in their efforts to reduce the risk of harm. Ways to minimize radiation exposure include reducing time of exposure, increasing the distance from the radiation source, and utilizing adequate shielding.

Conclusion and future trends

Radiation treatment uses ionizing radiation to treat malignancies as a primary therapy, or, more importantly now, as part of a planned collaborative multidisciplinary approach, used in combination with systemic therapy and surgery. Like surgery, it is a local therapy, and has a curative, adjuvant, or palliative role in managing most cancers. Although acute toxicities are reversible, late toxicities are not, and are related mostly to the loss of normal fibrosis mechanisms. The risk of radiation-induced malignancy, as well as other late side effects, becomes more important as more cancers are cured, and the proportion of survivors grows.

Dramatic advances in radiation treatment planning, delivery, and verification technology have increased the accuracy and precision of treatment, allowing higher doses to tumor,

and reducing the risk of radiation injury by sparing more normal tissue. Improvements in RT-planning systems provide not only the ability to apply dose constraints to specified structures, but also to provide data that help quantify risk of toxicity, in tandem with better reporting and collection of data and outcomes. These approaches all contribute to improving the prevention of radiation injury. Radioprotection also occurs by reducing risk of radiation damage through modification of delivery techniques, but modulating radiation cellular response is of greater importance. Although this concept has been studied for years, clinical results have been disappointing; nevertheless, a new generation of biological modifiers offers greater hope. However, the future of radiation oncology lies in biology, and specifically bioengineering and tissue regeneration, and the imperative to repair the damage that has already been caused.

Results of a survey regarding irradiation of internal mammary chain in patients with breast cancer: practice is culture driven rather than evidence based. *Int J Radiat Oncol Biol Phys.* 2004;60:706–714. There is great variation in the use of radiation to treat the internal mammary chain (IMC) of lymph nodes in patients with breast cancer. There is little definitive data, making this a controversial issue. These patterns of practice were examined in a case-based survey of radiation oncologists across North America and Europe. All respondents were more likely to treat the IMC if the axillary nodes were involved, and European and Academics in North America were also more likely to treat the IMC. However, the study also demonstrated how the greatest influence on decision-making was the local culture, and the value and preference that was placed on interpretation of local data.

68. Tubiana M. Can we reduce the incidence of second primary malignancies occurring after radiotherapy? A critical review. *Radiother Oncol.* 2009;91:4–15, discussion 1–3. Second primary malignancies (SPMs) occurring after oncological treatment have become a major concern during the past decade. Their incidence has long been underestimated because most patients had a short life expectancy after treatment or their follow-up was shorter than 15 years. With major improvement of long-term survival, longer follow-up, cancer registries and end-result programs, it was found that the cumulative incidence of SPM could be as high as 20% of patients treated by radiotherapy. This cumulative proportion varies with several factors, which ought to be studied more accurately. The delay between irradiation and solid tumor emergence is seldom shorter than 10 years and can be as long as half a century. Thus, inclusion in a cohort of patients with a short follow-up leads to an underestimation of the proportion of SPM caused by treatment, unless actuarial cumulative incidence is computed. The incidence varies with the tissue and organs, the age of the patient at treatment, hereditary factors, but also, and probably mainly, with dose distribution, size of the irradiated volume, dose, and dose-rate. An effort toward a reduction in their incidence is mandatory. Preliminary data suggest that SPMs are mainly observed in tissues having absorbed doses above 2 Gy (fractionated irradiation) and that their incidence increases with the dose. However, in children thyroid and breast cancers are observed following doses as low as 100 mGy, and in adults lung cancers have been reported for doses of 500 mGy, possibly due to interaction with tobacco. The dose distribution and the dose per fraction have a major impact. However, the preliminary data regarding these factors need confirmation. Dose-rates appear to be another important factor. Some data suggest that certain patients, who could be identified, have a high susceptibility to radiocancer induction. Efforts should be made to base SPM reduction on solid data and not on speculation or models built on debatable hypotheses regarding the dose-carcinogenic effect relationship. In parallel, radiation therapy philosophy must evolve, and the aim of treatment should be to deliver the minimal effective radiation therapy rather than the maximal tolerable dose.

68. Tubiana M. Can we reduce the incidence of second primary malignancies occurring after radiotherapy? A critical review. *Radiation Oncol.* 2009;91:4–15, discussion 1–3. *Second primary malignancies (SPMs) occurring after oncological treatment have become a major concern during the past decade. Their incidence has long been underestimated because most patients had a short life expectancy after treatment or their follow-up was shorter than 15 years. With major improvement of long-term survival, longer follow-up, cancer registries and end-result programs, it was found that the cumulative incidence of SPM could be as high as 20% of patients treated by radiotherapy. This cumulative proportion varies with several factors, which ought to be studied more accurately. The delay between irradiation and solid tumor emergence is seldom shorter than 10 years and can be as long as half a century. Thus, inclusion in a cohort of patients with a short follow-up leads to an underestimation of the proportion of SPM caused by treatment, unless actuarial cumulative incidence is computed. The incidence varies with the tissue and organs, the age of the patient at treatment, hereditary factors, but also, and probably mainly, with dose distribution, size of the irradiated volume, dose, and dose-rate. An effort toward a reduction in their incidence is mandatory. Preliminary data suggest that SPMs are mainly observed in tissues having absorbed doses above 2 Gy (fractionated irradiation) and that their incidence increases with the dose. However, in children thyroid and breast cancers are observed following doses as low as 100 mGy, and in adults lung cancers have been reported for doses of 500 mGy, possibly due to interaction with tobacco. The dose distribution and the dose per fraction have a major impact. However, the preliminary data regarding these factors need confirmation. Dose-rates appear to be another important factor. Some data suggest that certain patients, who could be identified, have a high susceptibility to radiocancer induction. Efforts should be made to base SPM reduction on solid data and not on speculation or models built on debatable hypotheses regarding the dose-carcinogenic effect relationship. In parallel, radiation therapy philosophy must evolve, and the aim of treatment should be to deliver*

- the minimal effective radiation therapy rather than the maximal tolerable dose.*

Pathophysiology of lymphedema

Raghu P. Kataru, Daniel A. Cuzzzone, and Babak J. Mehrara

SYNOPSIS

- Lymphedema is a progressive disease that can occur as a result of congenital defects, iatrogenic injury, or infection of the lymphatic system.
- The lymphatic system is comprised of capillary lymphatics that drain into progressively larger collecting vessels.
- The pathology of lymphedema is due to accumulation of lymphatic fluid leading to chronic inflammation, fibrosis, and adipose deposition.
- Obesity and radiation significantly increase the risk of lymphedema after surgery.

Introduction

Lymphedema is a progressive disease of the lymphatic system characterized by chronic inflammation, adipose deposition, hyperkeratosis, and fibrosis. Although the precise mechanisms regulating the development of lymphedema remain unknown, a key inciting event is lymphatic dysfunction and impaired clearance of interstitial fluids. As a result, lymphedema can develop due to genetic/developmental abnormalities of the lymphatic system (i.e. primary lymphedema) in which lymphatic vessels are absent or poorly developed. Primary lymphedema may also occur secondary to pathologic processes that directly impair lymphatic function. More commonly, lymphedema develops after trauma or infection of the lymphatic system (secondary lymphedema). These inciting events set off a cascade of tissue changes that in some cases ultimately results in massive accumulation of adipose tissue and the classic findings of elephantiasis (Fig. 27.1).

Estimates of the incidence of lymphedema vary widely. Some studies report as many as 200 million patients in developing countries who suffer from lymphedema secondary to parasitic infections by *Wuchereria bancrofti*. This disease has a variable course with smoldering disease in some and rapidly progressive/disabling lymphedema in others. Case reports of

massive extremity or scrotal lymphedema in patients with filariasis have been reported resulting in significant morbidity and mortality.

In the United States and Europe, the most common cause of lymphedema is cancer treatment. Breast cancer survivors comprise the largest group of affected individuals due to the high incidence of breast cancer in these regions. It is estimated that as many as 30–60% of breast cancer patients treated with axillary lymph node dissection go on to develop lymphedema.^{1,2} Recent advances in sentinel lymph node biopsy have decreased the requirement for full axillary lymph node dissection and have decreased the incidence of lymphedema. However, lymphedema does develop even after sentinel lymph node biopsy in 5–7% of patients.^{3,4} Lymphedema is not exclusively a disease of breast cancer survivors and occurs as a complication of treatment of most other solid tumors, most commonly gynecological cancers, melanoma, pelvic tumors, and sarcomas. In fact, a recent meta-analysis estimated that nearly 1 in 6 patients treated for a variety of solid tumors go on to develop lymphedema.^{5,6} The development of lymphedema in patients with sarcomas is an interesting phenomenon since lymph nodes are rarely removed in these tumors, suggesting that widespread injury to the superficial lymphatic system (as would occur with a wide excision of a skin sarcoma in combination with radiation therapy) can sufficiently disrupt the lymphatic vasculature and lead to the development of lymphedema even when the regional lymph nodes are not injured.

Anatomy and physiology

Lymphatic circulation

The lymphatic system plays a key role in a number of physiologic processes including interstitial fluid and immune cell transport, regulation of inflammation, responses to host or foreign antigens, and fat absorption, among others. The

transport of immune cells and interstitial fluid from the periphery begins in capillary lymphatics located in the dermis (Fig. 27.2). These vessels are comprised of a single layer of lymphatic endothelial cells (LECs) that are physically tethered to the surrounding tissues by anchoring filaments and to each

other by overlapping or intercalating button-like junctions. Minute changes in tissue fluid content causes adjacent LECs to separate due to the physical connections of these cells with the surrounding tissues by anchoring filaments, thus enabling entrance of cells and interstitial fluid into the initial lymphatics. Once the interstitial fluid has entered the lymphatic system, the overlapping regions between LECs is re-established maintaining the fluid within the lymphatic vessel. Fluid is propelled passively to pre-collectors and collecting lymphatics located in the deeper dermis and subcutaneous tissues. The LECs in collecting vessels, in contrast to the capillary lymphatics, have continuous endothelial cell junctions that prevent fluid leak with physical changes in the microenvironment. In addition, collecting lymphatics have a basement membrane and are covered by smooth muscle cells that can contract to propel lymphatic fluid forward. Lymphatic collectors also have bicuspid valves located every 1–2 mm that ensure one-way flow of interstitial fluid blocking backflow into the capillary lymphatic system. The functional lymphatic unit is defined as a lymphangion and contains a region of collecting lymphatic vessel between two valves (Fig. 27.3).

Lymphatic flow is determined by two factors. Passive compressive forces arise from external compressive forces such as muscle contractions, respiration, regional arterial pulsation, and gravity. These forces, as their name implies, passively propel interstitial fluid centrally. In normal limbs (i.e. without history of lymphatic injury), passive compressive forces such as massage or muscular contractions do not significantly increase lymphatic pressure in collecting lymphatics and do not increase flow. Active compressive forces arise from

intrinsic contraction of smooth muscle cells surrounding the collecting lymphatics. These muscle cells are unique in that they have features of both smooth and striated muscles and have basal myogenic activity. Myogenic forces in the lymphatic system, similar to the heart, are responsive to preload and afterload pressure changes. In addition, the force and frequency of lymphatic pump contraction can be modulated by vasoactive substances such as histamine and substance P, among others. In general, increases in preload and after load lead to an increase in contraction frequency and strength up to a point. Persistent increases beyond this point lead to lymphatic pump failure and vessel dilatation.

Lymph nodes

Lymph nodes filter lymphatic fluid as it is transported within the lymphatic system back to the venous circulation (Fig. 27.4). Although the number of lymph nodes is somewhat variable, a typical adult has 600–700 lymph nodes located in various regions and clustered in areas where body parts come together or in/around intra-abdominal organs. Interstitial fluid is transported centrally by collecting lymphatics and enters the subcapsular sinus of the lymph node via afferent lymphatics. From there, the interstitial fluid (and the antigens, antigen-presenting cells, and inflammatory cells it contains) drain through lymph sinuses that surround lymph node follicles where B cells reside. Lymphatic sinuses are lined by reticular endothelial cells and antigen-presenting cells enabling presentation and response to self/foreign antigens. Macrophages located in these regions can also phagocytose bacteria for processing and clearance. In addition, fluid exchange occurs through regional high endothelial venules that permeate the lymph node enabling hematogenous delivery of immune cells and cytokines to the lymph node. The lymphatic fluid exits the lymph node via efferent lymphatics located at the lymph node medulla progressing to the next lymph node chain or centrally for return back to the venous system.

Etiology of lymphedema

Primary lymphedema

Numerous genetic defects are associated with development of primary lymphedema (Table 27.1). These disorders have a highly variable natural history in terms of timing of presentation and severity of symptoms. In addition, primary lymphedema may be familial with known or suspected genetic defects, may occur as a result of spontaneous mutations, or in some cases develop without a known cause. Familial forms of primary lymphedema, even within members of the same family, can have different presentation due to the penetrance of the genetic mutation or causative factors and interaction with environmental regulators. Thus, in some cases primary lymphedema may present shortly after birth (i.e. congenital lymphedema) or, more commonly, become manifest years later with progressive symptoms (lymphedema praecox or lymphedema tarda).

In most cases of primary lymphedema, the lymphatic system is poorly developed with decreased numbers of lymphatic vessels (most commonly collecting lymphatics). It is unclear if patients with primary lymphedema have defects of the lymphatic system at birth or if these changes develop postnatally. The current evidence suggests that in most cases some degree of lymphatic dysfunction is present at birth and that these changes gradually worsen over time. The rate at which these changes occur is variable and can be altered by environmental factors leading to differential presentation of the disease. Studying these changes has been a challenge due to our inability to serially monitor the lymphatic system non-invasively; however, recent advances with lymphatic imaging have been helpful in this regard.

Congenital lymphedemas occur more commonly in females, more commonly involve the lower extremities, and account

Fig. 27.4 Schematic figure of a lymph node. Lymph enters the lymph node subcapsular sinus via afferent lymphatics and drains through the node via lymph sinuses, eventually exiting the node via the efferent lymphatics in the hilum. Blood capillaries and high endothelial venules enable leukocytes to enter the lymph node and are a site of fluid exchange.

Table 27.1 Genetic mutations and lymphedema

Gene	Syndrome	Pathology	References
<i>FLT4</i> (5q35) (coding region for <i>vascular endothelial growth factor receptor 3</i>)	Milroy disease	Primary lymphedema of the lower extremities. Upslanting “ski jump” toenails due to nail bed edema	64, 65, 81
<i>FLT4</i> (4q34) (coding region for <i>vascular endothelial growth factor C</i>)	Milroy-like lymphedema	Congenital lower limb lymphedema	73
<i>FOXC2</i>	Lymphedema-distichiasis syndrome	Lower-limb lymphedema most often presents at puberty; double row of eyelashes	72, 73, 82
<i>SOX18</i>	Lypotrichosis–lymphedema–telangiectasia syndrome	Lymphedema, hair loss, and small dilated blood vessels near the surface of skin	74
<i>GJC2</i> (coding for <i>connexin 47 (CX47)</i>)	Meige’s disease	Impaired gap junction activity, increased risk of breast cancer-related lymphedema	7
<i>CCBE1</i> (18q21) (encodes for <i>collagen & calcium binding EGF domain 1</i>)	Hennekam syndrome	Severe lymphedema in limbs, genitalia, and face; facial anomalies; seizures, mental retardation; and stunted growth. Symptoms often present <i>in utero</i>	75
<i>KIF11</i> (10q24)	MCLMR syndrome	Microcephaly, congenital lower limb LE, ocular abnormalities, learning disabilities	76
<i>GATA2</i> (3q21)	Emberger syndrome	Unilateral or bilateral lower limb lymphedema; presents in childhood; severe cutaneous warts; myelodysplasia	77
	WILD syndrome	WILD syndrome (warts, immunodeficiency, lymphedema, and dysplasia)	78
<i>AKT1</i>	Proteus syndrome	Lymphatic malformations, skeletal, cutaneous, and CNS abnormalities	79,80

for 10–25% of all primary lymphedemas.⁷ The degree of swelling of the limbs can be variable and in some cases may result in severe abnormalities in one limb and relatively mild or absent disease in the contralateral limb. Milroy's disease is a familial, sex-linked disorder in which inactivating mutations occur in the vascular growth factor receptor-3 (VEGF-R3). These mutations account for a relatively small number of patients with primary lymphedema (2–3%) and usually present shortly after birth with limb swelling and/or chylothorax. The pathophysiology of this disease arises from the fact that VEGF-R3 is primarily expressed by lymphatic endothelial cells and serves as a key signaling molecule for endothelial growth factor C (VEGF-C) and its closely related molecule VEGF-D. Activation of VEGF-R3 results in transmission of intracellular signals that regulate lymphatic endothelial cell differentiation, proliferation, migration, and endothelial-derived nitric oxide production. Not surprisingly, patients with Milroy's disease have hypoplastic lymphatic vessels with variable severity of dermal and collecting lymphatic vessel agenesis.

In contrast to congenital lymphedemas in which the disease presents shortly after birth, patients diagnosed with *lymphedema praecox* present with lymphedema at some point before the age of 35. The vast majority of these patients develop unilateral lower extremity lymphedema and the disease has a 4:1 female to male ratio. Additional evidence implicating a sex-hormone link with this disease is the fact that most patients begin to become symptomatic at the time of puberty.⁷ Histologic examination of patients with lymphedema praecox has shown variable pathologic findings; however, these patients often exhibit fewer capillary lymphatics and hypoplastic collecting vessels. Most patients present with unilateral lower extremity lymphedema (~70%) at some point between birth and age 35. These patients characteristically have decreased number and caliber of lymphatics and most commonly present during puberty with a female to male ratio of 4:1.

The diagnosis of *lymphedema tarda* refers to patients who develop primary lymphedema after the age of 35. This disease is a diagnosis of exclusion since secondary causes of lymphedema are much more common in this age group. In addition, lymphedema tarda is an infrequent presentation of primary lymphedema and occurs most commonly in the lower extremities of women. Although the pathophysiology of this disease remains largely unknown, recent studies have shown an association with loss-of-function mutations in the *FOXC2* gene.^{8–10}

The validity of classification schemes that categorize primary lymphedema based on the age at which symptoms present has been recently debated. This debate centers on the fact that presentation of these disorders is highly variable due to genetic and environmental factors and that this variability decreases the utility of these categories for diagnosis. As a result, recent studies have attempted to develop new classification schemes based on the presentation of disease and known genetic mutations.¹¹ This approach categorizes congenital lymphedemas into five main groups: syndromic, systemic or visceral, disturbed growth, congenital onset, and late onset. The developers of this system contend that this diagnosis algorithm is more precise and as a result can be useful for developing and testing of diagnostic or therapeutic interventions.

Secondary lymphedema

Secondary lymphedemas develop after injury or obstruction of the lymphatic system. For example, infections with parasites in filariasis results in chronic obstruction of lymphatic channels and subsequent immune responses that impair lymphatic function leading to progressive disease.¹² Filariasis is caused by roundworms (most commonly *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*) that are transmitted by mosquitos. The adult worms grow in the tissues and release larvae into the blood stream (microfilariae) that are diagnostic for the disease. However, patients with clinical disease may be free of microfilariae in the blood, in which case the diagnosis is made either clinically, or by tissue biopsies, or serum antigen testing. Filariasis is a major cause of morbidity in developing countries and treatment remains limited to anti-parasitic medications that only kill the developing larvae rather than the adult worm.

Iatrogenic lymphatic injury in the course of cancer treatment is another major cause of secondary lymphedema. In fact, lymphedema is the most common long-term complication of cancer treatment (even more common than radiation-induced sarcomas, or chemotherapy-induced renal or cardiac failure). Lymphedema can develop in the course of treatment for virtually all solid tumors including breast, gynecological tumors, melanoma, sarcoma, and pelvic tumors. Lymphedema can even develop after extirpation of head and neck tumors (4% incidence) resulting in cosmetic deformity and functional compromise.

Secondary lymphedema in cancer survivors occurs most frequently months and sometimes years after the initial surgery (Fig. 27.5). This delayed presentation together with the fact that lymphedema develops in only a subset of patients who undergo lymphadenectomy is important since these findings suggest that lymphatic injury is necessary but not sufficient for the development of the disease. Thus, additional pathological changes are needed for patients to develop lymphedema after lymph node dissection.

Fig. 27.5 Timing of lymphedema (linear prediction) presented as a scatterplot of median follow-up times of various studies. Note that development of lymphedema occurs in a delayed fashion after surgery. (From Cormier, et al. *Lymphedema beyond breast cancer: a systematic review and meta-analysis of cancer-related secondary lymphedema*. Cancer. 2010;116:5138–5149.)

On average, secondary lymphedema in breast cancer survivors develops approximately 8 months after the initial surgery.¹³ In addition, the majority of patients (75%) are diagnosed within the first 3 years.² In one unusual case report, a patient developed lymphedema after a seemingly innocuous injury 50 years after the initial lymphatic injury. Thus, in most cases the acute surgical swelling that develops after breast surgery and lymphadenectomy resolves within the first few weeks of surgery and, in most cases, never recurs. However, in some patients it recurs in a progressive and permanent manner 8–12 months later. This process appears to be accelerated somewhat in the lower extremity (perhaps due to the effect of gravity) with lymphedema developing on average 4–6 months after surgery.

Once lymphedema develops, it is usually progressive in nature with disease worsening over time. Although the rate of disease progression can be decreased with aggressive physical therapy and early diagnosis of lymphedema, some unfortunate patients progress rapidly even despite wrapping and aggressive symptomatic treatment. In addition, the rate of disease progression in patients with lymphedema in general is highly variable with some patients experiencing relatively indolent disease necessitating little to no compression while others progress rapidly to disabling disease that has little response to therapy.¹⁴ Although the efficacy of manual lymphatic massage has been debated, most studies suggest that these treatments are helpful in most patients, resulting in decreased symptomatology and diminished rate of progression. In addition, these interventions are most effective in early stage disease, therefore careful follow-up of patients who are at risk for disease has been advocated.

The rate of disease progression and severity of disease can be modulated by exercise and weight-loss programs. These interventions are effective in both prevention and treatment of lymphedema and should be encouraged in all at-risk individuals.^{15,16} Interestingly, for many years physicians and therapists warned patients who had undergone lymph node dissection to avoid strenuous exercise or weight lifting with their affected limb based on an idea that these activities would increase blood flow to the limb and in turn increase lymphatic load.² However, this myth was eventually disproven by a number of prospective randomized control studies demonstrating efficacy of weight loss and exercise in the treatment of lymphedema.^{17,18}

Diagnosis

The diagnosis of lymphedema is usually made by clinical exam and, in some cases, radiologic tests. The differential diagnosis of primary or secondary lymphedema includes venous insufficiency, congestive heart failure, malignancy (either recurrent or primary causing lymphatic obstruction), and infections. Patients with lymphedema often present with swelling, skin tightness, heaviness, and fatigue. More rarely, the presenting symptom is cellulitis and rapid swelling of the affected extremity. Limb circumference and volume measures are useful means of analyzing the degree of swelling in unilateral cases and these measures are commonly used as a means of following disease progression (Fig. 27.6). Differences of more than 2 cm or a volume differential of more than 200 cc is considered by most sources diagnostic of lymphedema,

Fig. 27.6 Lymphedema measurements. (A) Circumference measurements for upper extremity lymphedema. (B) Water displacement method for calculating limb volume. (Adapted from Pitsch F. Benefit of dalfon 500 mg in chronic venous disease related edema. *Phlebology*. 2006;13:17–21.)

with some schemes classifying patients based on measured differences.¹⁹ The use of measurements alone can be problematic in some cases due to the relative subjective nature of this test (i.e. a 2 cm difference in a thin patient is likely much more significant than a 2 cm difference in a morbidly obese individual). Nevertheless, measurements are a cornerstone of lymphedema diagnosis and treatment.

Circumference measurements are usually performed at defined intervals (in many cases 5 cm below and 5 cm above the olecranon); however, a wide range of measures have been reported. In addition, the inter and intra-operator validity of circumference measurements has been questioned although several reports have provided evidence that with training these measurements can be performed reproducibly. Limb volume measurements can be performed with water displacement; however, this approach can be difficult for practical purposes (for example some hospitals require using sterile fluid for each patient). The perometer is an infrared scanner that measures the limb circumference (arm or leg) in multiple areas and then uses the truncated cone formula to calculate limb volume and volume differentials (Fig. 27.7).^{20,21} This device is useful but is unfortunately expensive and not widely available in the United States. Limb volumes can also be calculated by measuring limb circumferences at 4 cm intervals and using the truncated cone formula as described by Brorson.²² This approach is simple to perform and is a good compromise between water displacement/perometer and limb circumference measurements.

Radiologic tests can be useful in the diagnosis of lymphedema. For example, lymphoscintigraphy is a procedure in which a radiolabelled colloid is injected in the distal extremity

Fig. 27.7 Lower limb (left) and upper limb (right) perometer measurements. (Adapted from Pero-systems Inc.)

and the rate/amount of uptake is then analyzed in the draining lymph node basins.^{23,24} Lymphoscintigraphy can also be used to estimate dermal backflow, a condition in which lymphatic blockage proximally results in the redirection of lymphatic fluid from deep channels into the superficial lymphatics. However, recent reports have suggested that the sensitivity of lymphoscintigraphy (0.61) for early stage lymphedema is lower than other methods such as MRI and indocyanine green (ICG) lymphangiography.²⁵ The lymphatic vessels and pathologic changes in lymphedema can also be visualized using MRI (MRI lymphangiography) with a high degree of sensitivity and specificity.^{25–27} However, this technique is user- and radiologist-dependent and requires optimization of techniques.

Recent studies have advocated the use of indocyanine green (ICG) near-infrared (NIR) lymphangiography in the diagnosis and staging of lymphedema. In this test, ICG dye is injected in the dermis of the affected extremity and lymphatic vessels are visualized using a NIR camera. It is important to note that the use of ICG is currently only FDA approved for intravenous injection and that intradermal injections for visualization of the lymphatic system are an off-label use. This method enables visualization of the superficial collecting lymphatics, dermal backflow, and abnormal lymphatic vasculature and is a helpful adjunct to the diagnosis of lymphedema. Recent reports have suggested that ICG lymphangiography has a high degree of sensitivity and specificity for diagnosing lymphedema and that pathologic changes such as splash/stardust/diffuse patterns are present even in early-stage disease (Fig. 27.8).²⁵ In fact, some authors have developed lymphedema staging systems based on ICG lymphangiography (see below).²⁸ Experimental reports have also shown that lymphatic pumping capacity (the rate of change in fluorescence intensity in a given vessel over time) can be a useful measure of lymphatic function; however, this analysis has not been widely adopted.

A few non-invasive methods are available for the diagnosis of lymphedema. For example, with bioimpedance, the rate of

Fig. 27.8 ICG anatomy of normal and lymphedematous limbs. (A) Collecting vessels are clearly identified in the normal dorsal hand (arrow points to injection site). (B) Lymphedematous hand with extensive dermal reflux and lack of clearly identifiable lymphatics.

Fig. 27.9 Bioimpedance measurement compares the rate of electrical transmission between the lymphedematous and normal limbs.

electrical current transmission through tissues, is used to estimate the fluid content of the lymphedematous limb as compared with the normal limb (Fig. 27.9).²⁹ Although this test can have variable results due to skin temperature, superficial skin dryness, and other factors, some studies

have suggested that bioimpedance is helpful in the diagnosis of early-stage lymphedema in which volumetric or circumference differences are subtle or non-existent. Finally, the degree of skin and soft tissue fibrosis can be estimated with a tonometer and followed longitudinally to monitor disease progression.^{30,31}

Lymphedema classification

Common classification systems for lymphedema rely primarily on the clinical features of the disease. The International Society of Lymphology staging system is the most widely used scheme and is based on measurable swelling and presence or absence of pitting (Fig. 27.10; Table 27.2).³² In this scheme, patients who have a history of lymphatic injury and present with symptoms of lymphedema (e.g. heaviness, fatigue) without swelling or measurable volume changes are classified as latent lymphedema (stage 0). Patients with stage I lymphedema (also known as spontaneously reversible lymphedema) have measurable swelling and pitting edema that improves with elevation or use of compression garments. Stage II lymphedema (spontaneously irreversible lymphedema) is characterized by accumulation of fibroadipose tissues that prevents reversal of symptoms by elevation or compression. Finally, patients with severe swelling, fibrosis, hyperkeratosis, and end-stage lymphedema symptoms are diagnosed with stage III or lymphostatic elephantiasis.³³

Changes in limb circumference or volume as compared to the contralateral limb or preoperative values have also been used as a means of classifying the severity of lymphedema.^{19,34} Although there is variability in these studies, the majority of reports classify patients with limb circumference excess of 2 cm or 100 cc volume differential as mild lymphedema. Differences of 2–4 cm (or more than 200 cc volume) is considered moderate lymphedema. Patients who have measured differences of 4 cm or more are classified as having severe lymphedema. The utility of this classification scheme, however,

Stage	Pathophysiology	Description
0	Latent lymphedema	Lymphatic vessels are injured. Capacity for fluid transport is impaired, but still sufficient to drain lymph as necessary. Lymphedema has not yet occurred or is not yet apparent.
I	Spontaneously reversible lymphedema	Pitting has started – the affected area indents when pressure is applied to it. Swelling can be contained with the use of compression garments.
II	Spontaneously irreversible lymphedema	Affected tissue is considered to be non-pitting and has a spongy consistency. Fibrosis starts to occur as the limbs harden and increase in size. At this point, compression garments are ineffective at suppressing symptoms.
III	Lymphostatic elephantiasis	Swelling is irreversible, and the tissue is heavily fibrosed and unresponsive to treatment. Skin has become significantly thickened.

is highlighted by the fact that it assumes that the limbs had equal circumference or volume preoperatively (a false assumption in many patients due to differences based on hand/leg dominance). In addition, not taking into account a patient's body habitus is problematic since a 2 cm difference is much more significant in a thin patient than in an obese patient.

ICG lymphangiography has been proposed by some researchers as a useful means of classifying patients with lymphedema. These efforts are important since they attempt to use physiologic changes in addition to clinical exam findings. Koshima *et al.* have proposed a system based on their experience with lymphovenous bypass procedures (Table 27.3). These authors classified the progression of secondary lymphedema into 4 steps based on ICG findings and termed this scheme the NECST system (Fig. 27.11).²⁸ The initial step in the disease process is normal lymphatic vessels distal to the zone of lymphatic injury. This is followed by lymphatic ectasis (dilated lymphatics with flattening of lymphatic endothelial cells), followed by contraction (loss of intraluminal diameter in collecting lymphatics and thickening of smooth muscle cell covering), and finally sclerosis (obliteration of the lumen with proliferative smooth muscle cells).

The M.D. Anderson classification scheme also classifies lymphedema into four stages based on ICG findings and quantification of dermal backflow (Fig. 27.12; Table 27.4).³⁵ In this scheme, stage 1 patients have numerous patent lymphatics and minimal/no dermal backflow. Stage 2 patients have a moderate number of lymphatics and segmental dermal backflow. Stage 3 patients have few patent lymphatics with significant dermal backflow throughout the entire arm. Finally, stage 4 patients have no patent lymphatics and severe dermal

Fig. 27.10 Patient with pitting edema of the upper extremity resulting from breast cancer-related lymphedema.

Table 27.3 Koshima lymphedema staging system

Type	Description
Normal type (Step 0)	Lymphatic vessels are normal and fully functional
Ectasis type (Step 1)	Endolymphatic pressure is noticeably increased, causing lymphatic endothelial cells to flatten. Lymphangiectasia, the dilation of lymphatic vessels, starts to occur
Contraction type (Step 2)	Smooth muscle cells are converted into synthetic cells, promoting collagenous fiber growth. The wall of the lymphatic vessel starts to thicken
Sclerosis type (Step 3)	Lumen of lymphatic vessels are narrowed if not completely obstructed. Most of the tissue is fibrosed, and lymphatic vessels have lost their ability to transport and concentrate lymphatic fluid

(Data from Mihara M, Hara H, Hayashi Y, et al. Pathological steps of cancer-related lymphedema: histological changes in the collecting lymphatic vessels after lymphadenectomy. *PLoS One*. 2012;7:e41126.)

Table 27.4 M.D. Anderson ICG lymphedema classification system.³⁵

Stage	Description
1	Many patent lymphatic vessels present and minimal dermal backflow can be observed in localized areas
2	Moderate number of lymphatic vessels can be seen with segmental dermal backflow
3	Few patent lymphatic vessels can be seen and significant dermal backflow can be observed throughout the entire arm
4	No patent lymphatic vessels can be seen. Severe dermal backflow throughout the entire arm and hand is apparent

backflow of the entire arm and hand. Although this scheme is somewhat subjective, the authors have found that it is useful for classification and patient selection for lymphovenous bypass procedures.

Pathophysiology of lymphedema

Although lymphedema is common and morbid, surprisingly little is known about the pathophysiology of this disease. The histological hallmarks of the disease are edema, fibroadipose tissue deposition, chronic inflammation, and hyperkeratosis and recent studies have begun to shed light on how lymphatic injury leads to these protean symptoms (Fig. 27.13). A key concept in understanding the pathology of lymphedema is that lymphatic injury is only the initiating step and that additional pathological events are necessary for the development of lymphedema clinically. This concept is highlighted by the fact that lymphedema only develops in a subset of

patients who undergo lymphadenectomy, and even in these individuals does so in a delayed fashion usually months to years after surgery. A better understanding of these pathological events is necessary for improved diagnosis and development of rational targeted treatment or prevention options. Although a number of studies have analyzed lymphatic vascular changes in primary lymphedema and have identified a wide variety of defects, the remainder of this discussion will be dedicated to pathophysiological changes that occur in secondary lymphedema following cancer therapy.

Lymphatic vascular defects in secondary lymphedema

Lymphangiographic studies performed acutely after axillary lymph node biopsy (i.e. before onset of lymphedema) demonstrate dilated collecting lymphatics and blockage of flow in these vessels in the axilla. Patients at this stage have subclinical interstitial fluid stasis that is either not clinically measurable (stage 0 or latent lymphedema) or resolves spontaneously with compression/elevation (stage I). Persistent subclinical interstitial fluid stasis results in further dilatation of the collecting lymphatics, lymphatic valvular incompetence, and retrograde flow to capillary lymphatics located in the superficial dermis (i.e. dermal backflow). At this point, the collecting lymphatics maintain the ability to actively contract, however the pulsations become more irregular with loss of correlation between lymphatic pulse amplitude and stroke volume.³⁶ Lymphatic stasis leads to activation of endogenous danger signals by local cells (adipocytes, endothelial cells, myocytes, and inflammatory cells) which in turn promote activation of chronic inflammatory pathways, expression of inflammatory cytokines, and further promotion of leukocyte entry into the lymphedematous tissues.³⁷

In the early stages of injury following lymph node dissection, chronic inflammation and subclinical lymphatic fluid stasis promote proliferation and collateralization of capillary lymphatics in the superficial dermis. These vessels effectively bypass the zone of obstruction and prevent development of overt lymphedema (Fig. 27.14).³⁸ However, in the fraction of patients (30–50%) who go on to develop clinically measurable lymphedema, sustained interstitial fluid stasis and ongoing chronic inflammation lead to extracellular matrix collagen deposition with resultant obliteration of capillary lymphatics and smooth muscle cell proliferation around collecting lymphatics.³⁹ Thus, we and others hypothesize that development of clinically evident lymphedema is dependent on the failure of both superficial and deep lymphatic systems (i.e. capillary and collecting lymphatics, respectively) (Fig. 27.15). Patients have overt accumulation of interstitial fluid in the subcutaneous tissues (stage II) and changes in limb volume or circumference become possible by conventional measures. Interstitial fluid accumulates primarily (60–70% of the total excess volume) in the subcutaneous tissues between adipose tissues and around small veins.⁴⁰ To a lesser degree, fluid also accumulates above/below the muscular fascia and in the dermis. Collecting lymphatic vessels at this stage continue to actively contract; however, these contractions are ineffective and fail to propel lymphatic fluid forward.

Progression of lymphedema occurs as a result of accumulation of adipose tissues, hyperkeratosis, fibrosis, and progressive destruction/dysfunction of the remaining lymphatic

Fig. 27.11 (A) NECST classification of lymphedema. Upper panel shows representative figures of patients with various stages of lymphedema. Lower panel shows collecting lymphatic vessels corresponding to these stages. Note progressive sclerosis of the collecting lymphatics. (B) Histological changes in collecting lymphatics in the NECST classification scheme. Note increasing deposition of smooth muscle actin around the lymphatic vessels with increasing stage. (Adapted from Mihara M, Hara H, Hayashi Y, et al. Pathological steps of cancer-related lymphedema: histological changes in the collecting lymphatic vessels after lymphadenectomy. PLoS One. 2012;7:e41126.)

vessels (i.e. late stage II to III disease) (Fig. 27.16). The proportion of fluid versus fat accumulation is variable in different individuals and can have widely different patterns of deposition in the limb although some regions tend to swell more than others (i.e. medial elbow area). In addition, progressive fibrofatty deposition makes lymphedema therapy more resistant to compressive therapies. This problem is compounded by the presence of absent pulsations or completely sclerosed collecting lymphatics with loss of luminal diameter⁴¹ and absence of spontaneous lymph flow.

Regulation of fibrosis

Based on the evidence cited above, it is clear that extracellular matrix fibrosis and progressive sclerosis of collecting lymphatics play a key role in the pathology of lymphedema. This idea also provides a rationale for the increased risk of lymphedema in patients who have undergone radiation therapy and is supported by experimental studies demonstrating that fibrosis independently decreases lymphatic vessel regeneration and lymphatic function.^{42,43} Lymphedema may therefore

Fig. 27.12 M.D. Anderson ICG lymphedema classification system. (A) Stage 1: many patent lymphatic vessels and minimal dermal backflow. Lymphatic territories (lymphosomes) in a canine: an animal model for investigation of postoperative lymphatic alterations. *PLoS One*. 2013;8:e69222.)

simply be a fibrotic disorder with loss of functional parenchyma (i.e. capillary and collecting lymphatics) due to progressive fibrosis.

Using a variety of mouse models as well as clinical biopsy specimens, our lab has shown that lymphedema results in progressive fibrosis and that inhibition of this fibrotic response markedly increases lymphatic regeneration and function. In addition, we have shown that fibrosis in lymphedema is mediated by a proliferation of CD4+ cells that differentiate into a particular type of T-helper cell (Th2 cell) which in turn produces vast amounts of profibrotic cytokines such as interleukin 4, interleukin 13, and transforming growth factor beta-1.⁴⁴⁻⁴⁶ Treatment of lymphedema patients with lympho-venous bypass procedures is not only associated with symptomatic improvement, but also decreased accumulation of

Fig. 27.15 Hypothetical model for development of lymphedema after failure of both deep and superficial lymphatic function.

Fig. 27.16 Cadaver dissection and lymphangiography in a patient with a history of unilateral axillary lymph node dissection. Note loss of capillary (superficial) lymphatics stained green in the upper limb after lymph node dissection. (Adapted from Suami H, Pan WR, Taylor GI. Changes in the lymph structure of the upper limb after axillary dissection: radiographic and anatomical study in a human cadaver. *Plast Reconstr Surg*. 2007;120:982-991.)

CD4+ cells and fibrotic tissue. This observation, together with our previous animal studies demonstrating that depletion of CD4+ cells or inhibition of Th2 profibrotic cytokines markedly decreases the symptoms of lymphedema, may serve as a useful clinical intervention. This approach is currently under investigation in a clinical trial using monoclonal antibodies. Thus, pharmacological interventions may be a viable means of treating lymphedema or may serve as an important adjunct to surgery.

Regulation of adipose deposition

The end stage of lymphedema is progressive fibroadipose deposition. Thus, the initial pathology of lymphedema is accumulation of interstitial fluid; however, over time this fluid promotes adipose deposition rendering compressive treatments for lymphedema obsolete. It is clear, therefore, that lymphatic (interstitial) fluid accumulation and adipose deposition are closely related.^{47,48} This idea is supported by previous studies demonstrating that interstitial fluid potentially increases adipocyte proliferation and differentiation *in vitro*.⁴⁹ In addition, our lab has previously shown that lymphedema results in proliferation and hypertrophy of local adipocytes and that even mild lymphatic injury promotes expression of adipocyte differentiation markers.^{49–51}

The relationship between adipocytes and lymphatic endothelial cells appears to be bidirectional in nature. This hypothesis is based on recent reports demonstrating that obesity markedly impairs lymphatic function both clinically and in animal models. In addition, recent studies have shown that super obese individuals (i.e. BMI >59) spontaneously develop lower extremity lymphedema and that this effect is permanent with little improvement after gastric bypass and weight loss. More recently our lab has shown that lymphatic function is directly proportional to body weight in mice and that a threshold exists beyond which abnormalities in the lymphatic system are easily measureable. These findings provide a rationale for the fact that obesity is a major risk factor for lymphedema.

Risk factors for lymphedema

A variety of genetic and environmental factors have been shown to increase the risk of developing lymphedema including obesity, radiation, infection, and genetic factors.^{3,52–58}

Obesity

Obesity is among the first recognized risk factors for lymphedema⁵⁹ and has since been shown to increase the risk of disease in patients treated for a variety of solid tumors. Prospective studies have shown that patients with a body mass index (BMI) of >30 have at least a threefold increased risk of developing lymphedema as compared with patients with a similar stage breast cancer but a BMI of <25.⁶⁰ Other studies have shown that this relationship is almost linear with higher baseline weight being correlated with development of lymphedema after axillary lymph node dissection for breast cancer.³ Greene and colleagues have shown that massively obese patients (BMI >59) in some cases spontaneously develop lower extremity lymphedema.⁶¹ Even postoperative weight gain in previously lean patients increased the risk

of lymphedema development. Further, randomized clinical trials have shown that diet-induced weight loss over a 12-week period resulted in a significant reduction in arm volumes as compared to controls who did not lose weight.⁶² Finally, exercise studies have shown monitored exercise programs in lymphedema patients not only led to weight loss but also markedly decreased lymphedema symptoms as compared to a sedentary control group. Thus, although the cellular mechanisms regulating the interaction between obesity and lymphatic function remains unknown, it is clear that a relationship does exist and that patients who are scheduled for lymphadenectomy or lymphatic surgery should be counseled to first lose weight prior to proceeding with invasive interventions.

Radiation

Radiation therapy in combination with surgery is also a well-known risk factor for development of lymphedema, increasing the risk of disease development by as much as fivefold.^{63–66} Interestingly, lymphedema is significantly more prevalent in obese patients treated with surgery and radiation, suggesting that risk factors for lymphedema can act in an additive manner.⁶⁷ Although some studies have failed to show a relationship between radiation and development of lymphedema after breast cancer treatments, some of these results may be confounded by the fact that radiation in some studies included only the chest wall and not the regional lymph node basins (e.g. supraclavicular or axilla). In addition, it appears that the negative effects of radiation on lymphedema development are largely additive to those of surgery since the development of the disease following radiation alone is unusual, occurring in less than 7% of patients.⁶⁶

Infection

Postoperative infections and cellulitis have long been thought to be a risk factor for development of lymphedema, however the mechanisms that regulate this potential interaction remain unknown. In addition, it is unknown if development of an infection is a symptom of subclinical lymphedema that eventually blossoms into full scale disease or if infection damages remaining lymphatics thus resulting in disease development. Nevertheless, previous gynecological reports have shown that early infections following vulvar cancer surgery significantly increase the incidence of lower extremity lymphedema development.⁶⁸ These findings have led some investigators to suggest that avoiding cellulitis is a major method to avoid lymphatic injury and disease progression, particularly in patients with a previous history of lymphedema.⁶⁹

Genetics

Genetics have long been shown to cause primary lymphedema and lymphatic abnormalities. However, more recent studies have identified genetic factors that also predispose patients to developing *secondary lymphedema*. For example, Finegold *et al.* found that women with mutations in the gene encoding for connexin 47 or hepatocyte growth factor have a significantly increased risk of developing lymphedema after mastectomy and axillary lymph node dissection as compared with normal controls.^{70,71} Another studied 157 single-nucleotide polymorphisms (SNPs) in 17 candidate genes and demonstrated that at least four genes and three haplotypes may contribute to

development of secondary lymphedema.⁷² By providing evidence for genetic mutations as an important risk factor in secondary lymphedema, these new discoveries challenge the traditional perspective of secondary lymphedema being solely due to mechanical trauma.⁷²

Summary

Lymphedema is a debilitating and common disease that occurs most commonly as a complication of cancer care.

Recent studies have shown that the pathophysiology of lymphedema is related to lymphatic vessel dilation, valvular incompetence, chronic inflammation and fibrosis. Treatment strategies aiming to decrease these changes (e.g. manual lymphatic massage or compressive pumps) decrease the rate of progression of disease and are helpful adjuncts to therapy. In addition, a better understanding of the pathophysiology of lymphedema may enable development of targeted preventative or therapeutic strategies.

Benign and malignant nonmelanocytic tumors of the skin and soft tissue

Rei Ogawa

Access video lecture content for this chapter online at expertconsult.com 

SYNOPSIS

- All typical skin and skin-associated soft-tissue tumors, apart from malignant melanocytic tumors (malignant melanoma), are described from the point of view of a plastic surgeon.
- Biopsies should only be performed for a clear purpose, such as for the differential diagnosis of benign tumors or to analyze the stage and grade of malignant tumors, which would allow the area to be resected to be determined.
- One current and useful model is the reconstructive matrix, which helps plastic surgeons to determine the best reconstructive solutions for their patients in the context of particular medical and socioeconomic environments by considering aspects of surgical complexity, technological sophistication, and patient surgical risk.

Introduction

The skin consists of the epidermis, which is derived during ontogeny from the superficial ectoderm, and the dermis, which is derived from the mesenchyme. Starting in the first 3–4 weeks of human ontogeny, cells derived from the neural crest migrate into the epidermis (Fig. 28.1) where they become melanocytes and Schwann cells; the latter associate with peripheral nerves in the skin. Later, the cutaneous appendages develop. These include hair, which originates from epidermal cells, and hair papillae, which are filled with mesenchyme; vessels and peripheral nerve endings also develop in the papillae. Other cutaneous appendages are the sebaceous glands, which are derived from the epithelial wall of the hair papillae, and the eccrine and apocrine sweat glands, which are also epidermal in origin. There are also soft tissues that are associated with skin, namely fat, muscles, and blood vessels (all of which have a mesenchymal lineage) and nerves (derived from neural crest cells). Thus, skin and skin-associated soft-tissue tumors can be classified simply into those that are of epithelial, cutaneous appendage, neural crest, and mesenchymal origin (Fig. 28.2).

In this chapter, all typical skin and skin-associated soft-tissue tumors apart from malignant melanocytic tumors (malignant melanoma) are described from the point of view of the plastic surgeon.

Diagnosis

Inspection and palpation

The diagnosis of skin tumors starts with inspection and palpation. The following information should be recorded: the number of lesions (solitary or multiple), the shape of the lesion (e.g., round, oval, polygonal, geographic, linear, annular), its size, its elevation status (e.g., narrow-pediced, wide-pediced, dome-like, hemispherical, flat elevated, umbilicated), its surface status (e.g., smooth, rough, papillary, granular, transudatory, xerophily, ulcerative, erosive, atrophic, lustrous, necrotic), its color (e.g., normal, yellow, pale yellow, erythematous, blackish brown, black, blue, depigmented, pigmented, hyperemic, livid), its hardness (e.g., soft, elastic soft, elastic hard, hard, bone-like hard, fluctuating), its alignment (e.g., localized, disseminated, centrifugal, systematized, singular, symmetric, asymmetric, bilateral), its site, whether there are any subjective symptoms (e.g., pain, itch, contracture sensation, numbness, burning sensation, cold sensation), and the time course of the appearance of the lesion (e.g., acute, subacute, chronic, temporary, recurrent). Color plays a particularly important role in the diagnosis of skin lesions (Box 28.1). The possibility of malignant tumors should be suspected at all times. If the shape, size, elevation status, or color of a lesion changes rapidly, a biopsy should be considered.

Dermoscopy

Dermoscopy is a specialized technique that employs a binocular microscope to observe the skin surface. It is useful for diagnosing pigmented lesions and is necessary for differentially diagnosing malignant melanoma and nevus. It is also

Fig. 28.1 The human embryo at 3–4 weeks.

required for the diagnosis of seborrheic keratosis, basal cell carcinoma (BCC) and vascular lesions. Marghoob *et al.*¹ has recommended the use of a revised two-step diagnostic algorithm, in which the first step is to differentiate melanocytic from nonmelanocytic pigmented lesions by using specific dermoscopic criteria. The second step is to differentiate between the various nonmelanocytic lesions by using other specific dermoscopic criteria (Fig. 28.3). The dermoscopic criteria that are used to diagnose melanocytic lesions, seborrheic keratosis, BCC, and vascular lesions are shown in Box 28.2.

Ultrasound and Doppler imaging

To observe skin lesions, high-frequency ultrasound around 20–50 MHz is needed.² However, if the lesion shows extension

perpendicular to the skin surface that exceeds a depth of 20 mm, the standard ultrasound (3–10 MHz) should be used. In such cases, computed tomography (CT) and magnetic resonance imaging (MRI) can provide additional information. Ultrasound can be used to determine tumor thickness, its relationship with adjacent structures, and the presence of lymph node metastasis. A variety of ultrasound devices are suitable for this purpose, including mechanical or electron scanning, one-dimensional A-mode, two-dimensional B-mode, and three-dimensional C-mode devices.

Doppler imaging using color Doppler imaging (CDI) or power Doppler imaging is useful for the differential diagnosis of benign and malignant skin tumors, assessing inflammatory reactions, and detecting lymph node metastases. This is because 90% of malignant skin tumors exhibit a high blood flow rate of 3–20 cm/s that is not observed in more than 95%

Fig. 28.2 Development of the skin. (A) The fifth week of fetal life. (B) The seventh week of fetal life. (C) The fourth month of fetal life. (D) At birth.

BOX 28.1 Typical skin tumor colors**Normal color**

Epidermal origin (e.g., epidermoid cyst)
 Mesenchymal origin (e.g., lipoma, soft fibroma, leiomyoma)
 Neural crest origin (e.g., schwannoma)

Yellow–pale yellow

Appendage origin (e.g., sebaceous nevus, xanthoma, milia)

Erythematous

Epidermal origin (e.g., inflammatory atheroma, squamous cell carcinoma)
 Mesenchymal origin (e.g., keloid and hypertrophic scars, vascular malformations, hemangioma, dermatofibrosarcoma protuberans, angiosarcoma)

Blackish brown–black

Epidermal origin (e.g., basal cell carcinoma)
 Neural crest origin (e.g., pigmented nevus, melanoma)

Blue

Epidermal origin (e.g., epidermoid cyst)
 Neural crest origin (e.g., nevus of Ota, Mongolian spot, blue nevus)

BOX 28.2 Dermoscopic criteria used to diagnose melanocytic lesions, seborrheic keratosis, basal cell carcinoma, and vascular lesions**Criteria for melanocytic lesions**

Pigment network
 Negative network
 Aggregated globules
 Streaks
 Homogeneous blue pigmentation
 Pseudonetwork
 Parallel pattern

Criteria for seborrheic keratosis

Multiple milia-like cysts
 Comedo-like openings
 Light-brown fingerprint-like structures
 Fissures/ridges

Criteria for basal cell carcinoma

Pigment network is absent and one of:
 Arborizing vessels
 Leaf-like areas
 Large blue-gray ovoid nests
 Multiple blue-gray globules
 Spoke wheel areas
 Ulceration

Criteria for vascular lesions

Red–blue lacunas
 Red–bluish to red–black homogeneous areas

(Reproduced from the Consensus Net meeting on Dermoscopy, 2000. Available at: <http://www.dermoscopy.org/consensus/>.)

Fig. 28.3 Two-step diagnosis using dermoscopy. BCC, basal cell carcinoma. (Modified from Consensus Net meeting on Dermoscopy. Available at <http://www.dermoscopy.org/consensus/>.)

of benign skin tumors. The resolution of power Doppler imaging is higher than that of CDI. M-mode and duplex (a combination of B- and M-mode) scanning are useful for observing hemangiomas or vascular malformations.

X-ray, CT, MRI, angiography, scintigraphy, and positron emission tomography (PET)

X-ray analysis is useful for detecting calcifying lesions such as pilomatricoma and malignant tumors that have necrosis-induced calcifications. Moreover, bone deformation associated

with malignant or nonmalignant tumor invasion into bones can be observed by using X-rays.

CT detects metastatic lesions in the bone, lymph nodes, and lungs better than MRI. Helical CT or multidetector low CT can generate three-dimensional and high-resolution images. Contrast-enhanced CT and CT angiography are useful for detecting malignant tumors, vascular regions, and adjacent vascular structures.

MRI detects soft tissues better than CT. In general, malignant tumors present with low-iso signal intensity on T2-weighted images (T2WI) and low signal intensity on T1-weighted images (T1WI), while benign tumors exhibit high signal intensity on T2WI and low signal intensity on T1WI. Magnetic resonance angiography is superior to MRI in determining the nidus and exact nature of the collateral structures in hemangiomas and vascular malformations.

Angiography is an invasive imaging method that was frequently used in the past to investigate vascular lesions. While it detects hemangiomas and vascular malformations readily, its use with pediatric patients requires general anesthesia.

Scintigraphy can be used for metastatic lesion screening. ^{67}Ga and $^{201}\text{TlCl}$ are used in tumor- or inflammation-seeking scintigraphy, while $^{99}\text{Tc-MDP}$ and $^{99\text{m}}\text{Tc-HMDP}$ are used in bone scintigraphy. Scintigraphy suffers from low resolution, and this makes it difficult to detect lesions that are less than 2 mm in diameter by this method.

PET is also useful for detecting the metastatic lesions of malignant skin tumors.³ 2-deoxy-2-[^{18}F] fluoro-D-glucose (FDG) PET (FDG-PET) has been used for the diagnosis and staging of cancers and for monitoring treatment, particularly with regard to Hodgkin's lymphoma, non-Hodgkin's lymphoma, and lung cancer. PET can also sometimes detect many other types of solid tumors that occasionally show up as very highly labeled lesions. FDG-PET is particularly useful for searching for tumor metastasis, or for recurrence after the removal of a primary tumor that was known to be highly active. However, since PET can also detect inflammatory lesions, it will be necessary to exclude the possibility that a PET-detected apparent tumor is not an inflammatory, erosive, or ulcerated area.

Pathologic diagnosis

A definitive diagnosis requires a pathologic diagnosis. However, biopsies should only be performed for a clear purpose, such as for the differential diagnosis of benign tumors or to analyze the stage and grade of malignant tumors, which would allow the area to be resected to be determined. Moreover, biopsies should only take place after careful inspection, palpation, and imaging analyses. Depending on the purpose of a biopsy and the lesion characteristics, the surgeon can choose from a range of different biopsy techniques, including punch, incisional, excisional, and mapping biopsies. In the case of incisional biopsies, normal skin should be excised together with early-stage lesions and the characteristic areas of lesions (e.g., inflammatory, erosive, or ulcerated areas).

In the case of a possible malignant tumor, an excisional biopsy is recommended to prevent malignant cell dissemination into blood. However, surgeon judgment is needed to determine the amount of normal skin that should be removed. In general, the normal skin margin of an excisional biopsy should be as minimal as possible, especially if the tumor is suspected to be benign. However, if the margins of an excisional biopsy of a malignant tumor are wide enough, such biopsies could actually serve the same purpose as radical resections. Such extensive excisional biopsies could also reduce the number of operations that are needed to treat a tumor. Thus, if a low-grade malignant tumor (e.g., BCC) is suspected, an excisional biopsy that includes several millimeters of normal skin margin may be considered. For high-grade malignant tumors, excisional biopsies will often lead to a pathologic diagnosis that indicates the need for additional wide resection, radiation therapy, and/or chemotherapy.

Sentinel node biopsy is increasingly being used to detect lymph node metastasis, as it shows whether the cancer has spread to the very first lymph node.⁴ If the sentinel lymph node does not contain cancer, it is highly likely that the cancer has not spread to any other area of the body. However, this technique is only of therapeutic value for patients with positive nodes: for patients who have negative nodes, the possibility

that the lymph node has undetectable cancerous cells should be considered. In addition, there is no compelling evidence that the survival of patients who have a full lymph node dissection as a result of a positive sentinel lymph node biopsy is better than that of those patients who do not have a full dissection until later in the disease, when the lymph nodes can be felt by a physician. Thus, such patients may be subjected unnecessarily to full dissection, which is associated with lymphedema.

The TNM clinical classification system and the pTNM pathologic classification system

The TNM clinical classification^{5,6} applies only to malignant tumors (Figs. 28.4 & 28.5). T indicates the size of the tumor and whether it has invaded nearby tissue, N indicates whether regional lymph nodes are involved, and M indicates the presence of distant metastasis. The TNM classification system is based on clinical evidence acquired before definitive treatment. Once intraoperative and surgical pathologic data become available, the pathologic TMN (pTNM) classification system can be used. The pT, pN, and pM categories correspond to the T, N, and M categories.

Regional lymph nodes are those that drain the site of the primary tumor (Fig. 28.6). The pN assessment of the regional lymph nodes requires that a sufficient number of lymph nodes are removed for histologic examination (usually six or more). If the examined lymph nodes are negative but fewer than six lymph nodes were resected, the pN classification is designated pN0.

Box 28.3 shows examples of the TNM classification system, namely the systems used for eyelid, vulva, penis, and soft-tissue sarcomas.

Clinical staging

The TNM system^{5,6} is used to show the anatomical extent of malignant tumors. For purposes of tabulation and analysis, it is useful to condense these categories into stages (Table 28.1). To be consistent with the TNM system, carcinoma *in situ* is categorized as stage 0. In general, tumors that are localized to the organ of origin are categorized as stages I and II, while those that exhibit extensive local spread, particularly to the regional lymph nodes, are classified as stage III. The tumors that have distant metastasis are classified as stage IV. For pathological stage groups, if sufficient tissue has been removed for pathological examination to evaluate the highest T and N categories, M1 may be either clinical (cM1) or pathological (pM1). However, if only a distant metastasis has had microscopic confirmation, the classification is pathological (pM1) and the stage is pathological.

Treatment

Wide excision

With regard to wide resection of malignant tumors of skin, the horizontal and vertical margins vary depending on the type of tumor.⁷⁻⁹ Retrospective histopathologic studies have supported reductions in the horizontal margin in recent

T – Primary tumor*

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	The greatest dimension of the tumor is 2 cm or less
T2	The greatest dimension of the tumor is more than 2 cm but less than 5 cm
T3	The greatest dimension of the tumor is more than 5 cm
T4	The tumor invades deep extradermal structures such as cartilage, skeletal muscle, or bone

* In the case of multiple simultaneous tumors, the tumor with the highest T category is used for the classification and the number of separate tumors is indicated in parentheses (e.g., T2 (5))

Fig. 28.4 The T factor of the TNM classification system, as described by the Union for International Cancer Control (UICC). (Used with the permission of the Union for International Cancer Control (UICC), Geneva, Switzerland. Original source: Wittekind CF, Greene FL, Hutter RVP, et al. TNM Atlas: Illustrated Guide to the TNM/pTNM Classification of Malignant Tumours, 5th edition. Berlin: Springer; 2004.)

years. The horizontal margins that are recommended for particular tumor types are listed in [Box 28.4](#). In the case of malignant soft-tissue tumors, the type of excision can vary with regard to the extent of the margins around the tumor: curative wide, wide, and marginal excisions indicate margins that are at least 5 cm outside the tumor-reactive layer, 1–2 cm outside the tumor-reactive layer, and within the tumor-reactive layer, respectively. It is now considered that wide excision is the appropriate margin for soft-tissue sarcoma. Moreover, Mohs micrographic surgery, where tumors undergo histologic analysis during surgery in such a way that almost all of the surgical margins can be examined for tumor extensions, can help to obtain complete margin control during the removal of a skin cancer and soft-tissue sarcoma.¹⁰

Lymph node dissection

Axillary lymph node dissection

Since sentinel lymph node biopsy is now a widely practiced technique, there are fewer occasions where preventive axillary lymph node dissection is necessary. Metastatic squamous cell carcinoma (SCC) is an example of a malignant nonmelanocytic skin tumor that warrants axillary lymph node dissection. Axillary lymph nodes can be classified into levels I, II, and III, which relate to the lateral and internal edges of the pectoralis minor muscle. Level I is the bottom level and lies below the lower edge of the pectoralis minor muscle. Level II lies underneath the pectoralis minor muscle, while level III is above the pectoralis minor muscle. Structures that should be preserved

Fig. 28.5 The N and M factors of the TNM classification system, as described by the Union for International Cancer Control (UICC). (Used with the permission of the Union for International Cancer Control (UICC), Geneva, Switzerland. Original source: Wittekind CF, Greene FL, Hutter RVP, et al. TNM Atlas: Illustrated Guide to the TNM/pTNM Classification of Malignant Tumours, 5th edition. Berlin: Springer; 2004.)

during axillary lymph node dissection are the pectoral nerves, the long thoracic nerve, the intercostobrachial nerves, the axillary artery and veins, the thoracoacromial artery and veins, and the subscapular artery and veins.

Inguinal lymph node dissection

Widespread use of sentinel lymph node dissection has also reduced the frequency of inguinal lymph node dissection. Representative indications for inguinal lymph node dissection

are metastatic SCC and extramammary Paget's disease (EMPD). Traditionally, the area of dissection is a triangle composed of the inguinal ligament, the internal edge of the sartorius muscle, and the internal edge of the long adductor muscle. In the wide resection of inguinal lymph nodes, the femoral vein is identified along with the saphenous vein. After clamping the saphenous vein, the adductor longus muscle is identified and should be cleaned of all fatty nodal tissue by retracting the saphenous vein *en bloc* with the lymph nodes until the adductor canal is reached.

Unilateral tumors

Head, neck	Ipsilateral preauricular, submandibular, cervical, and supraclavicular lymph nodes
Thorax	Ipsilateral axillary lymph nodes
Upper limb	Ipsilateral epitrochlear and axillary lymph nodes
Abdomen, loins, and buttocks	Ipsilateral inguinal lymph nodes
Lower limb	Ipsilateral popliteal and inguinal lymph nodes
Anal margin and perianal skin	Ipsilateral inguinal lymph nodes

Tumors in the boundary zones

Between

Right / left midline

Head and neck / thorax	Clavícula–acromion–upper shoulder blade edge
Thorax / upper limb	Shoulder–axilla–shoulder
Thorax / abdomen, loins, and buttocks	Front: middle between the navel and the costal arch. Back: lower border of the thoracic vertebrae (midtransverse axis)
Abdomen, loins, and buttocks / lower limb	Groin–trochanter–gluteal sulcus

Fig. 28.6 The regional lymph nodes, as described by the Union for International Cancer Control (UICC). (Used with the permission of the Union for International Cancer Control (UICC), Geneva, Switzerland. Original source: Wittekind CF, Greene FL, Hutter RVP, et al. TNM Atlas: Illustrated Guide to the TNM/pTNM Classification of Malignant Tumours, 5th edition. Berlin: Springer; 2004.)

Reconstructive surgery

Reconstruction via skin grafting is a basic surgical technique that is used to reconstruct the tissue defects that occur after tumor extirpation, which is also useful for early detection of local recurrence. The ideal approach after tumor extirpation is to suture the wound margins directly together. However, this can only be performed if the wound is not too big and the adjacent skin can be extended sufficiently. One concern with this approach is that malignant cells may be left in the deep margins of the wound. Recent developments in reconstructive techniques, including thin flap-based techniques and wound coverage materials, mean that plastic surgeons can now choose from a wide and rapidly evolving variety of primary and aesthetic secondary reconstruction methods. Given this constantly altering medical (and social) environment, it is difficult

to develop up-to-date reconstructive algorithms, and indeed, previous algorithms such as the reconstructive ladder, elevator, and triangle quickly lose favor. Consequently, the techniques that are chosen for primary and secondary reconstruction are largely determined on a case-by-case basis. However, one current and useful model is the reconstructive matrix,¹¹ which helps plastic surgeons to determine the best reconstructive solutions for their patients in the context of particular medical and socioeconomic environments by considering aspects of surgical complexity, technological sophistication, and patient surgical risk.

Radiation therapy

Malignant tumors vary in their sensitivity to radiation-induced damage, which directly affects the success of radiation therapy.

BOX 28.3 The TNM classification systems for eyelid, vulva, penis, and soft-tissue sarcomas (Union for International Cancer Control)**Carcinoma of the skin of the eyelid**

- TX Primary tumor cannot be assessed
- T0 No evidence of primary tumor
- Tis Carcinoma *in situ*
- T1 The tumor is of any size and does not invade the tarsal plate; or the tumor is at the eyelid margin and its greatest dimension is 5.0 mm or less
- T2 The tumor invades the tarsal plate; or the tumor is at the eyelid margin and its greatest dimension is more than 5.0 mm but less than 10.0 mm
- T3 The tumor involves the full eyelid thickness; or the tumor is at the eyelid margin and its greatest dimension is more than 10.0 mm
- T4 The tumor invades adjacent structures, including the bulbar conjunctiva, sclera/globe, soft tissues of the orbit, perineural invasion, bone/periosteum of the orbit, nasal cavity/paranasal sinuses, and central nervous system
- N1 Regional lymph node metastasis

Carcinoma of the skin of the vulva

- TX Primary tumor cannot be assessed
- T0 No evidence of primary tumor
- Tis Carcinoma *in situ*
- T1 The tumor is confined to the vulva, or the vulva and the perineum, and its greatest dimension is 2 cm or less
- T1a The tumor is confined to the vulva, or the vulva and perineum, its greatest dimension is 2 cm or less, and it exhibits stromal invasion that is no greater than 1.0 mm
- T1b The tumor is confined to the vulva, or the vulva and the perineum, its greatest dimension is 2 cm or less, and it exhibits stromal invasion that is greater than 1.0 mm
- T2 The tumor is confined to the vulva, or the vulva and the perineum, and its greatest dimension is more than 2 cm
- T3 The tumor invades the lower urethra, vagina, and/or anus
- T4 The tumor invades the bladder mucosa, rectal mucosa, and/or upper urethral mucosa, or is fixed to the pubic bone
- NX Regional lymph nodes cannot be assessed
- N0 No regional lymph node metastasis
- N1 Unilateral regional lymph node metastasis
- N2 Bilateral regional lymph node metastasis

Carcinoma of the skin of the penis

- TX Primary tumor cannot be assessed
- T0 No evidence of primary tumor
- Tis Carcinoma *in situ*
- Ta Noninvasive verrucous carcinoma
- T1 The tumor invades the subepithelial connective tissue
- T2 The tumor invades the corpus spongiosum or cavernosum
- T3 The tumor invades the urethra or prostate
- T4 The tumor invades other adjacent structures
- NX Regional lymph nodes cannot be assessed
- N0 No regional lymph node metastasis
- N1 Metastasis in a single superficial inguinal lymph node
- N2 Metastasis in multiple or bilateral superficial inguinal lymph nodes
- N3 Metastasis in deep inguinal or pelvic lymph nodes, unilateral or bilateral

Soft-tissue sarcoma

- TX Primary tumor cannot be assessed
- T0 No evidence of primary tumor
- T1 The greatest dimension of the tumor is 5 cm or less
- T1a The tumor is superficial*
- T1b The tumor is deep*
- T2 The greatest dimension of the tumor is more than 5 cm
- T2a The tumor is superficial
- T2b The tumor is deep
- N1 Regional lymph node metastasis

*Superficial tumors are located exclusively above the superficial fascia and do not invade the fascia, while deep tumors are either exclusively beneath the superficial fascia, or are superficial to the fascia but invade into or through the fascia. Retroperitoneal, mediastinal, and pelvic sarcomas are classified as deep tumors. (Modified from Sobin LH, Gospodarowicz MK, Wittekind C (eds). *TNM Classification of Malignant Tumours (UICC: Union for International Cancer Control)*, 7th edn. Chichester: Wiley-Blackwell; 2009; and Wittekind CF, Greene FL, Hutter RVP, et al (eds). *TNM Atlas: Illustrated Guide to the TNM/pTNM Classification of Malignant Tumours*, 5th edn. Berlin: Springer; 2004.)

For example, malignant melanomas are less sensitive to radiation and are therefore rarely treated with radiation therapy. Malignant skin tumors that are relatively sensitive to radiation and are therefore commonly treated with radiation therapy include BCC,¹² SCC,¹³ and Merkel cell carcinoma of the skin.¹⁴ Acute skin reactions to radiation therapy occur during the first 7–10 days after treatment and are characterized initially by erythema that then progresses to pigmentation, epilation, and desquamation; this is particularly the case when higher doses are used. Subacute and late complications occur several weeks after radiation therapy and can progress for long periods of

time. These complications include scarring, permanent pigmentation, depigmentation, atrophy, telangiectasis, subcutaneous fibrosis, and necrosis.

Chemotherapy

Chemotherapy can be either adjuvant or primary, and all chemotherapies can be administered either systemically or topically. Adjuvant chemotherapy is mainly used for malignant melanoma, while primary chemotherapy is indicated for SCC,¹⁵ angiosarcoma,¹⁶ and EMPD.¹⁷ However, the radical

BOX 28.4 Recommended surgical margins of wide excisions of nonmelanocytic tumors of the skin and soft tissues**Horizontal margin**

Basal cell carcinoma

low risk: 4 mm

high risk: 5–10 mm

Squamous cell carcinoma

low risk: 4–6 mm

high risk: 10 mm

Merkel cell carcinoma

10–20 mm

Sarcoma

low risk: 10 mm

high risk: 20 mm

Vertical margin**With fat layer**

Tumors that are limited to the dermis

With deep fascia

Tumors that extend into the fat layer

With skeletal muscle

Tumors that extend into the deep fascia

With the membranes of deeper structures such as cartilage or bone

Tumors that extend into skeletal muscle

With deeper structures like cartilage or bone

Tumors that extend into membranes of deeper structures like cartilage or bone

Others

The margins of wide tumor excisions that occur in anatomically complicated and special regions (e.g., eyelid, vulva, penis, finger/toe tip, and ear) will vary on a case-by-case basis. This is also true for soft-tissue tumors. In general, at least one layer of barrier structure should be excised. For example, for tumors that are limited to the fat layer, the deep fascia of skeletal muscle is considered as the barrier structure and should be removed with the tumor upon wide excision.

chemotherapy that malignant skin tumors are generally treated with can sometimes be seen as neoadjuvant chemotherapy before surgery for advanced stage cancer. Single-agent chemotherapies include peplomycin sulfate and CPT-11¹⁸ for SCC, paclitaxel for angiosarcoma, and docetaxel for angiosarcoma and EMPD. Multiagent chemotherapies includes cisplatin + doxorubicin and cisplatin + 5-fluorouracil (5-FU) + bleomycin for SCC; mesna + doxorubicin + ifosfamide + dacarbazine for angiosarcoma; and 5-FU + mitomycin C, 5-FU + carboplatin + leucovorin, and 5-FU + carboplatin + mitomycin C + epirubicin + vincristine for EMPD.

Laser therapy

Dye lasers or neodymium-doped yttrium aluminum garnet (Nd:YAG) lasers can be used for lesions that are characterized by neoplastic changes or malformations in capillary vessels or

their overgrowth, such as hemangiomas,¹⁹ vascular malformations,²⁰ and keloid/hypertrophic scars.²¹ Ruby and alexandrite lasers can be used to treat superficial pigmented lesions whose colors range from brown to black, while Q-switched ruby and alexandrite lasers are useful for intradermal pigmented lesions such as the nevus of Ota.²² CO₂ lasers and erbium yttrium aluminum garnet (Er:YAG) lasers target the water content of a lesion,²³ which makes them suitable for lesions with various colors like seborrheic keratosis, telangiectatic granuloma, xanthoma, and fibroma.

Others (including immunotherapy, cryotherapy, electrocoagulation therapy, and sclerotherapy)

At this stage, the only indication for immunotherapy is malignant melanoma. Cryotherapy and electrocoagulation therapy induce the freezing and melting of the tumor tissues, which results in their necrosis and/or apoptosis; these methods are suitable for superficial benign or malignant tumors like seborrheic keratosis, fibroma, and BCC. Sclerotherapy, where a sclerosant like ethanol, ethanolamine oleate, polidocanol, or OK-432 is injected into affected vessels, can be used to treat vascular malformations. Promising technologies that may become useful in the near future include: hyperthermic infusion therapy, where the tumor is infused with a substance that makes it more susceptible to locally applied heat; molecular target therapy, which involves drugs or other substances that block the growth and spread of the tumor by interfering with specific tumor growth and progression molecules; and gene therapy and gene cell therapy, where genes are manipulated in target healthy cells (to enhance their cancer-fighting properties) or in target cancer cells (to kill them or inhibit their growth).

Benign cutaneous and soft-tissue tumors**Benign epithelial-origin tumors***Epidermal nevus (e.g., verrucous epidermal nevus and linear epidermal nevus)*

This nevus is composed of skin cells that normally occur at the affected site but show hyperkeratosis and papillomatosis (Fig. 28.7). It can be considered to be a hamartoma, which is a benign focal, tumor-like malformation that is composed of a mixture of the cells that characterize the tissue of its origin;

Fig. 28.7 Epidermal nevus of the upper arm.

such nodules grow at the same rate as the surrounding tissues. The dermis below the epithelial nevus is usually normal. Epithelial nevi sometimes exhibit a diffuse or extensive distribution that affects a large area of the patient's body (termed systematized epidermal nevus); careful observation is necessary in these cases. Systematized epidermal nevus often occurs together with abnormalities in other organ systems. This condition is termed epidermal nevus syndrome,²⁴ and has been described as a sporadic neurocutaneous linkage of congenital ectodermal defects in the skin, brain, eyes, and/or skeleton. Laser therapy, cryotherapy, electrocoagulation, surgical abrasion, and excision are suitable for treating epithelial nevi. If abrasion therapy is used, it should be remembered that these lesions are usually limited to the epidermis; thus, to prevent heavy scarring, only the epidermis and the superficial layer of the dermis should be removed.

Seborrheic keratosis (also known as senile wart)

This is a benign skin growth that originates from the basal and squamous cells in the epidermis (Fig. 28.8). It should be differentiated from nevus cell nevus, senile keratosis, BCC, and malignant melanoma. The sign of Leser-Trélat, which is the dramatic, sudden appearance of multiple seborrheic keratoses, can be a paraneoplastic syndrome, namely an ominous sign of an internal malignancy.²⁵ In such cases, not only do new lesions suddenly appear, pre-existing lesions also frequently increase in size and become symptomatic. This sign should not be overlooked and screening for internal malignancy should be recommended to the patient. Laser therapy, cryotherapy, electrocoagulation, surgical abrasion, and excision are all suitable treatments for seborrheic keratosis. However, if the tumor invades the dermis, which can occur, surgical excision is recommended.

Keratoacanthoma

Keratoacanthoma has been a controversial entity for many years, mainly because it closely resembles SCC²⁶ (Fig. 28.9). It grows rapidly and can sometimes self-heal. Upon histopathology, atypical squamous cells can be detected, which makes it difficult to distinguish from SCC. For this reason, excisional biopsy should be considered despite the fact that this lesion

Fig. 28.9 Keratoacanthoma on the nose.

occasionally self-heals. If the lesion is on the nose and face, Mohs micrographic surgery is particularly suitable since it facilitates good margin control along with minimal tissue removal.

Epidermoid cyst (also known as epidermal cyst and atheroma)

Epidermal cyst is a smooth, dome-shaped, freely movable, somewhat fluctuant subcutaneous swelling that is sometimes attached to the skin by a central pore (Fig. 28.10). It is covered with a stratified squamous epithelium that resembles the epidermis or the follicular infundibulum; thus, there is a granular cell layer adjacent to the keratin-containing cyst lumen. Epidermoid cysts can rupture spontaneously or be ruptured by external mechanical forces. Extremely large epidermoid cysts, also known as giant atheromas (Fig. 28.11), should undergo pathology to rule out malignant change,²⁷ although such changes are rare. Epidermoid cysts that exhibit inflammation or recur should be removed by simple excision. In the case of large cysts, the contents can be removed first, after which the cyst walls can be removed with minimal

Fig. 28.8 Seborrheic keratosis on the temporal region.

Fig. 28.10 Epidermoid cyst with a central pore.

Fig. 28.11 Giant atheroma.

incision (Fig. 28.12). In cases where pus and blood are excreted, the surgeon should consider incising the cyst and draining it first, and then excising it completely 1–2 weeks later.

Milia

Milia are a smaller version of an epidermoid cyst (less than 4 mm in diameter). They may derive from the outer root sheath of vellus follicles. There are primary and secondary milia.²⁸ Primary milia include congenital milia, benign primary milia of children and adults, milia en plaque, nodular grouped milia, multiple eruptive milia, nevus depigmentosus with milia, and genodermatosis-associated milia. Secondary milia are the disease-, medication-, and trauma-associated milia. Milia can be treated easily by making small holes in the surface with a needle or CO₂ laser and then extruding the contents.

Dermoid cyst

A dermoid cyst is a congenital subcutaneous cyst that develops along the embryonic lines of closure (Fig. 28.13). It is most common on the head and neck area, particularly the supraorbital region, brow, upper eyelid, glabella, and scalp. These cysts can be easily removed surgically, but care should be taken not to injure the temporal branch of the facial nerve. The cyst lumen contains keratin debris and hair shaft fragments. Preoperative X-rays should be taken to distinguish it

from pilomatricoma on the head and neck region, especially in pediatric patients. Since it has been reported that dermoid cysts can exhibit malignant changes, complete surgical removal is recommended.²⁹

Others

Rare benign epidermal-origin skin tumors include clear cell acanthoma, large cell acanthoma, acantholytic acanthoma, warty dyskeratoma, traumatic inclusion cyst, human papillomavirus-associated cyst, proliferating epidermal cyst, and cutaneous keratocyst. The preoperative diagnosis of these tumors can be difficult, but many can be treated radically with a simple excision and suture.

Benign appendage-origin tumors

Nevus sebaceus

Nevus sebaceus is a hamartoma rather than a neoplasm (Fig. 28.14). It is essentially confined to the head and neck regions, and can be found not only in the sebaceous gland but also in the epidermis, dermis, hair follicles, and sweat glands. Consequently, it is also referred to as organoid nevus. In appearance, it resembles an epidermal nevus. Since other tumors such as BCC and trichilemmoma can arise from nevus sebaceus over time,³⁰ complete surgical excision is recommended. If it is located in the hair, the hair stream should be carefully considered while performing the excision and suturing; moreover, dehairing caused by unnecessary buried or dermal sutures should be avoided.

Pilomatricoma (also known as calcifying epithelioma and pilomatrixoma)

This is a cystic nodule that tends to occur on the head and neck regions of young patients (Fig. 28.15). Multiple pilomatricoma may be seen in a familial setting in patients who also have myotonic dystrophy. A calcified region can be seen by ultrasound, X-ray, CT and MRI. This region will appear as a high-intensity signal on ultrasound, while on MRI it will show up as a low-intensity signal on both T1WI and T2WI. Since malignant tumors sometimes have a calcified lesion that is caused by necrosis, it is necessary to exclude this possibility when making a diagnosis of pilomatricoma. It is not associated with a clear capsule and thus should be excised carefully and completely to prevent recurrence. Malignant

Fig. 28.12 An epidermoid cyst (A) and the removal of the cyst with a minimal incision (B, C).

Fig. 28.13 (A) Dermoid cyst on the supraorbital region. (B) The excised cyst.

pilomatricoma has been reported,³¹ but there have been less convincing reports of the carcinomatous transformation of pre-existing benign pilomatricoma.

Trichilemmal cyst

This is a subcutaneous cyst that is derived from the outer root sheath of the hair follicle and arises most frequently on the hairy region on the head (Fig. 28.16). Clinically, it resembles an epidermoid cyst. Multiple cysts on the head are seen in 70% of cases. Complete excision is recommended. The conservative approach involves a small punch biopsy of the cyst that allows the cyst cavity to be entered. The contents of the cyst can then be emptied, leaving an empty cyst wall that can be grasped with a forceps and pulled out of the small incision. This method often results in a very small scar and very little, if any, bleeding. Proliferating trichilemmal cyst is an uncommon lesion that is characterized histologically by trichilemmal keratinization. It is thought to originate from a trichilemmal cyst and to have the potential for malignant transformation, at which point it is termed a malignant proliferating trichilemmal cyst.³²

Syringoma

Syringoma is the result of intradermal eccrine proliferation that is malformative rather than neoplastic in most cases. It

occurs mainly on the eyelids and presents as a 1–2-mm nodule. Since the main reason for treating syringoma is cosmetic, the tumor should be destroyed in such a way that there is minimal scarring and no recurrence. For this purpose, electrocoagulation, dermabrasion, CO₂ lasers, Er:YAG lasers, and fractional photothermolysis³³ can be used, although attention should be paid to preventing pigmentation and scarring.

Apocrine cystadenoma (also known as apocrine cysthidroma)

Apocrine cystadenoma is characterized by the dilatation of an apocrine duct and secondary proliferation of the ductal epithelium that is architecturally bland (Fig. 28.17). Apocrine cystadenomas appear most commonly as solitary, soft, dome-shaped, and translucent papules or nodules. They are located most frequently on the eyelids, especially the inner canthus. They grow slowly and usually persist indefinitely. They can be incised and drained, but electrosurgical destruction of the cyst wall is often needed to prevent recurrence. Punch, scissors, or elliptical excision

Fig. 28.14 Nevus sebaceus on the scalp.

Fig. 28.15 Pilomatricoma on the upper eyelid.

Fig. 28.16 Solitary trichilemmal cyst on the scalp (A) and after its excision (B).

can also remove these tumors. Multiple cystadenomas can be treated with a CO₂ laser. Trichloroacetic acid³⁴ has also been used.

Chondroid syringoma (also known as cutaneous mixed tumor)

Chondroid syringoma derives from the sweat glands and is most frequently seen on the head and neck, where it presents as an unexceptional dermal or subcutaneous nodule (Fig. 28.18). The tumor consists of a gland-like epithelial component that is set in a chondromyxoid stromal component. It is believed that there are both eccrine and apocrine variants. Hirsch and Helwig proposed the following five histologic criteria for diagnosis: (1) nests of cuboidal or polygonal cells; (2) intercommunicating tubuloalveolar structures lined with

two or more rows of cuboidal cells; (3) ductal structures composed of one or two rows of cuboidal cells; (4) occasional keratinous cyst; and (5) a matrix of varying composition. Since malignant forms have been reported, although they are rare, complete surgical excision is recommended.³⁵

Others

Other benign appendage-origin tumors include steatocystoma multiplex (Fig. 28.19), trichofolliculoma, trichoepithelioma, poroma folliculare, trichilemmoma, sebaceous adenoma, eccrine nevus, and apocrine nevus. Moreover, hair follicles, sebaceous glands, and sweat glands (apocrine and eccrine glands) can undergo hyperplasia that results in a hamartoma; these skin appendages can also develop adenomas, benign epitheliomas, and primordial epitheliomas.

Fig. 28.21 Intradermal nevus on the lower eyelid.

Benign neural crest-origin tumors

Pigment cell nevus (also known as pigmented nevus and nevus cell nevus)

These are acquired and congenital nevi that originate from melanocytes. It has been suggested that healthy adults have on average 5–10 nevi. Dome-like elevated nevi sometimes bear hair. If an acquired nevus has a diameter of more than 7 mm and it is still growing, the possibility of malignant melanoma should be considered. It seems now that malignant melanomas do not originate from pigment cell nevus (except in the case of congenital giant nevus) but rather derive directly from epidermal melanocytes; this is known as the *de novo* carcinogenesis theory.³⁶ There are five types of pigmented nevi, as follows.

Lentigo simplex

Lentigo simplex is a black–brown pigmented nevus, 2–3 mm in diameter. It is believed to be an acquired pigment cell nevus that is at an early stage (Fig. 28.20). Its margins can be either jagged or smooth. It is the result of the proliferation of melanocytes in the basal layer of epidermis. It is not induced by sun exposure and is not associated with systemic disease. The lesions are few in number and may occur anywhere on the skin or mucous membranes. They usually first appear in early childhood around 3 years of age, but they can also be present at birth or develop later. Cryosurgery, lasers,³⁷ and simple excision can be tried.

Acquired pigment cell nevus

Acquired pigment cell nevi are due to the proliferation of melanocytes and can be divided into three types according to the location of the melanocytes. In junction nevi, the melanocytes are mainly located at the junction between the epidermis and dermis. In compound nevi, the melanocytes are located in the dermis as well as at the junction between the epidermis and dermis. In intradermal nevi (Fig. 28.21), the melanocytes are in the dermis only. Laser treatment is ineffective for melanocytes located in the deeper layer of dermis because these cells lack the melanin pigment. Thus, simple surgical excision is recommended to prevent recurrence. The nevus

that has a depigmented area around it is called Sutton's halo nevus.³⁸

Congenital pigment cell nevus

The congenital pigment cell nevus is present at the time of birth and increases in size as the body grows, although its shape does not change. It is classified according to size into the small type (less than 1.5 cm in diameter), medium type (1.5–20 cm in diameter), and large or giant type (over 20 cm in diameter) (Fig. 28.22). Histology shows that the nevus cells tend to be diffusely distributed in the deep layer of the dermis. Careful observation is needed because malignant melanomas can arise from giant congenital pigmented cell nevi.³⁹ Nevi that present on both the upper and lower eyelids are called divided nevi, while hairy giant nevi are called animal-skin nevi (Fig. 28.23). Giant nevi should be removed and reconstructed by the serial excision method, skin grafting, local flaps, or a combination of these.

Dysplastic nevus (also known as Clark's nevus and atypical mole)

Clinically, dysplastic nevus resembles an early-stage malignant melanoma.⁴⁰ It was initially thought to be a prodrome of

Fig. 28.22 Medium-type congenital pigment cell nevus on the shoulder.

Fig. 28.23 Animal-skin nevus.

malignant melanoma but is now suggested to be a type of acquired pigment cell nevus. Complete excision and pathologic examination should be performed. The US National Institutes of Health Consensus Conference on the diagnosis and treatment of early melanoma defined the familial atypical mole and melanoma syndrome,⁴¹ the criteria for which are the occurrence of malignant melanoma in one or more first- or second-degree relatives, the presence of numerous (often >50) melanocytic nevi, some of which are clinically atypical, and the presence of certain histologic features in many of the associated nevi.

Juvenile melanoma (also known as Spitz nevus)

This is a dome-like nodule that is about 1 cm in diameter and occurs on the face or legs of young patients (Fig. 28.24).⁴² The surface is smooth and sometimes exhibits telangiectasia. It may be nonpigmented or have a color that ranges from pink to orange-red. Some lesions are pigmented, especially those on the lower extremities. After its appearance, the lesion tends

to grow rapidly and may reach a size of 1 cm within 6 months. After this rapid initial growth phase it tends to become static, although color changes may be observed. Bleeding and pruritus are rare. Complete excision and pathologic examination should be performed.

Nevus spilus (also known as café-au-lait spot)

This is a benign tumor of melanocytes that is characterized by the increased accumulation of melanin granules rather than the proliferation of melanocytes (Fig. 28.25). The whole nevus has a uniform café-au-lait color. The presence of six or more nevus spilus lesions that are greater than 5 mm in diameter in prepuberty and over 15 mm in diameter in postpuberty is indicative of neurofibromatosis type 1 (NF1), also known as von Recklinghausen's disease (Fig. 28.26). NF1 is caused by a mutation of the chromosome band 17q11.2, which encodes neurofibromin. Neurofibromatosis type 2 (NF2) patients rarely have nevus spilus lesions and do not demonstrate the cutaneous neurofibromas that typically result in the early diagnosis of NF1, although they may have cutaneous schwannomas that resemble skin tags. Moreover, because symptoms from cranial nerve VIII schwannomas usually begin in the third decade of life, patients with NF2 are typically diagnosed later in life than patients with NF1.⁴³

Becker's melanosis (also known as Becker's pigmented hairy nevus)

This lesion is characterized by the slight proliferation of melanocytes in the basal layer of the epidermis, the increasing accumulation of melanin granules, and the presence of hair. It mainly occurs in males and develops at puberty, which suggests that androgens may play a role in its development. This is supported by the fact that it is associated with hypertrichosis, the occasional development of acneiform lesions within the patch, and, albeit rarely, with an accessory scrotum in the genital region. In addition, it has been reported that Becker melanosis lesional skin has significantly more androgen receptors than the normal surrounding skin. Ruby lasers, CO₂ lasers, and Er:YAG lasers can be used to treat Becker's melanosis.⁴⁴

Fig. 28.24 Spitz nevus on the cheek.

Fig. 28.25 Solitary nevus spilus on the knee.

Fig. 28.26 Nevus spilus on the thigh of patient with neurofibromatosis type 1.

Fig. 28.27 Nevus of Ota.

Nevus of Ota (also known as nevus fuscoceruleus ophthalmomaxillaris and oculodermal melanocytosis)

This is a blue nevus that arises from the first and second branches of the trigeminal nerve (Fig. 28.27). It is common in Asians and rare in Caucasians. Women are nearly five times more likely to be affected than men. It is not congenital but appears during early infancy and puberty.⁴⁵ It is caused by the proliferation of melanocytes in the dermis. Bilateral nevus of Ota also exists: this is called acquired bilateral nevus of Ota-like macules or late-onset dermal melanocytosis. It has been suggested that nevus of Ota may be derived from melanocytes that have not migrated completely from the neural crest to the epidermis during embryogenesis. The variable prevalence among different populations suggests a genetic influence, but familial cases of nevus of Ota are exceedingly rare. The two peak ages of onset in early infancy and early adolescence suggest that hormones are a factor in the development of this condition. Q-switched ruby or alexandrite lasers have been used to treat nevus of Ota.⁴⁶ After 4–8 treatments, the degree of skin pigmentation is reduced dramatically. Cryotherapy, dermabrasion, or peeling can also be used as a multimodal therapy on a case-by-case basis.

Nevus of Ito

This dermal melanocytosis can be considered as a subtype of nevus of Ota (Fig. 28.28). It occurs on the acromiodeltoid

region.⁴⁷ Its pathogenesis is unclear, but the fact that the dermal melanocytes of the nevus of Ito are in close proximity with nerve bundles suggests the nervous system may be a factor in its development. Recommended treatments are the same as those for nevus of Ota.

Mongolian spot (also known as congenital dermal melanocytosis)

More than 90% of Native American, 80% of Asian, and 70% of Hispanic infants have this proliferative disorder of dermal melanocytes, which presents as bluish-gray spots on the sacral and coccygeal region (Fig. 28.29). Fewer than 10% of Caucasian infants have Mongolian spots. These spots disappear before the age of 10 years. The blue-gray color is due to the melanocytes that are deep in the skin. It usually presents as multiple spots or one large patch covering the lumbosacral area (lower back), buttocks, flanks, and/or shoulders (Fig. 28.30). It results from the entrapment of melanocytes in the dermis during their migration from the neural crest to the epidermis during embryonic development.⁴⁸ Treatment is usually not necessary, but Q-switched alexandrite laser can be used for severe cases.

Blue nevus

Like the nevus of Ota and the Mongolian spot, this is a dermal melanocytosis. However, it involves more cells, which means it has a nodular form. There are three types: common, cellular, and combined.⁴⁹ The cellular lesion is usually larger than the common lesion and tends to invade the subcutaneous tissue. The combined lesion is a blue nevus that is combined with a pigment cell nevus or a juvenile melanoma. A biopsy should be performed to determine the proper diagnosis. For a solitary lesion, simple excision is usually curative. There are rare cases of persistent blue nevi that manifest as satellite lesions around the original excision site. These must be distinguished from malignant blue nevus and re-excision is recommended.

Fig. 28.29 Typical Mongolian spot on an Asian infant.

Fig. 28.30 Atypical Mongolian spot on the back.

Fig. 28.31 Schwannoma on the popliteal region.

Neuroma

Neuromas are hamartomas composed of peripheral nerve components, namely Schwann cells, fibroblasts, and axons; they arise as a result of ineffective, unregulated nerve regeneration that leads to neurofiber hyperplasia. They are often the result of nerve injury, especially injuries sustained during surgery; both superficial (skin or subcutaneous fat) and deep (e.g., cholecystectomy) surgery can induce neuromas. Neuromas are often very painful. It should be noted that neuroma is often used as a general term to describe any swelling of a nerve; thus, it does not necessarily mean neoplastic tumors. An example of this more general usage of the term is Morton's neuroma, which is a mononeuropathy of the foot; to avoid confusing it with a tumor, this condition is now often referred to as Morton's metatarsalgia.⁵⁰ Surgical removal is the treatment of choice for neuromas.

Schwannoma (also known as neurilemmoma)

This is a benign proliferation of Schwann cells in the dermis or subcutaneous tissues (Fig. 28.31). NF2 is associated with multiple schwannomas. Pathology shows that there are two basic histological types of schwannoma called Antoni types A and B. Type A is characterized by numerous Verocay bodies. These are acellular, eosinophilic areas that are oval, linear, or serpiginous in shape and are surrounded by parallel-lying or palisading bundles of spindled Schwann cells with blunt, elongated nuclei. In each Verocay body, the long axes of the cells are all oriented toward the acellular area. Type B lacks Verocay bodies and consists of a loose, myxomatous stroma with fewer and more randomly arranged spindle cells. Neither type appears to have neurites. Schwannomas are typically encapsulated and the associated peripheral nerve may be seen in the microscopic section. Occasionally, older lesions show degenerative changes such as hemorrhage, hemosiderin deposition, mild chronic inflammatory cell infiltration, dense fibrosis, and nuclear pleomorphism. Such ancient schwannomas⁵¹ are benign but must be differentiated from neurofibrosarcoma and malignant schwannoma. Surgical removal is the first choice of treatment.

Neurofibroma

A neurofibroma is a benign tumor of the peripheral nerve sheath. It is usually found in individuals with the genetically inherited diseases NF1 and NF2, and can result in symptoms that range from physical disfiguration and pain to cognitive disability (Figs. 28.32 & 28.33). Neurofibromas arise from Schwann cells but also incorporate many other types of cells and structural elements, which makes it difficult to identify and understand all the pathogenic mechanisms. Neurofibromas should be removed surgically or treated with a CO₂ laser. However, once a plexiform neurofibroma⁵² has undergone malignant transformation, radiation and chemotherapy can be used as adjuvant therapies.

Others

Other benign neural crest-origin tumors include the granular cell tumor and rudimentary polydactyly. The latter often have normal Merkel cells in the basal portion of the epidermis in addition to the proliferation of nerve fibers and encapsulated corpuscles. The proliferation of various neural components may be the essential feature of this condition.

Fig. 28.32 Mild neurofibroma on a patient with neurofibromatosis type 1.

Fig. 28.33 Severe neurofibroma on a patient with neurofibromatosis type 1.

Benign mesenchymal-origin tumors

Dermatofibroma (also known as fibrous histiocyoma)

Dermatofibroma is a common cutaneous nodule that frequently develops on the extremities (mostly the lower legs). It is usually asymptomatic, although pruritus and tenderness are not uncommon. It is characterized by the proliferation in the dermis of both fibroblasts and other cell types, including histiocytes (skin macrophages) and vascular endothelial cells. It can be divided into the cellular type, which is mainly characterized by histiocyte proliferation, and the fibrous type, which predominantly shows fibroblast proliferation. Strong endothelial cell proliferation can sometimes be observed in both types, in which case a diagnosis of sclerosing hemangioma is made (Fig. 28.34). Moreover, if the cellular components are small and the tumor is composed of hyalinized collagenous fibers, it can be called a sclerotic fibroma. There are many other special dermatofibroma forms, including hemosiderotic histiocyoma, xanthomatous histiocyoma, atypical

dermatofibroma, aneurysmal dermatofibroma, myxoid dermatofibroma, and keloidal dermatofibroma.⁵³ Removal of the tumor is not necessary unless diagnostic uncertainty exists or particularly troubling symptoms are present.

Xanthoma

Xanthoma is characterized by the aggregation of foamy histiocytes that have phagocytized lipids (Fig. 28.35). The most common xanthoma occurs on the upper eyelid and is often associated with hyperlipidemia. Xanthomas are not always associated with underlying hyperlipidemia but when they are, it is necessary to diagnose and treat the underlying lipid disorders to decrease the xanthoma size and reduce the risk of atherosclerosis. Treatment of the hyperlipidemia initially entails dietary changes and the use of lipid-lowering agents such as statins, fibrates, bile acid-binding resins, probucol, or nicotinic acid. Eruptive xanthomas usually resolve within weeks of initiating systemic treatment, while tuberous xanthomas usually resolve after a few months. However, tendinous xanthomas take years to resolve or may persist indefinitely. While the main goal of therapy for hyperlipidemia is to reduce the risk of atherosclerotic cardiovascular disease, in patients with severe hypertriglyceridemia the goal is to prevent pancreatitis. Surgery or locally destructive modalities, including lasers, can be used for idiopathic or unresponsive xanthomas.⁵⁴

Juvenile xanthogranuloma

This is a single or multiple dome-like tumor that occurs on the head and neck region, the body, or the limbs of young patients. Approximately 35% of cases of juvenile xanthogranuloma occur at birth, with as many as 70% of cases occurring in the first year. Most juvenile xanthogranulomas resolve by the age of 5 years. Despite the term “juvenile” in the disease name, 10% of cases manifest in adulthood (Fig. 28.36). Histologic analysis can reveal the presence of Touton giant cells (Fig. 28.37). This tumor can be associated with NF1, Niemann–Pick disease, urticaria pigmentosa, and juvenile chronic myelomonocytic leukemia.⁵⁵ The lesions can be excised for diagnostic and cosmetic reasons.

Fig. 28.37 Touton giant cell in a juvenile xanthogranuloma.

Fig. 28.38 Acrochordon.

Fig. 28.39 Fibroma pendulum.

Soft fibroma

There are three types of soft fibroma: (1) acrochordon (also known as a skin tag) (Fig. 28.38), which occurs on the neck and axilla and increases after middle age; (2) fibroma pendulum⁵⁶ (Fig. 28.39), which is a large fibroma over 10 mm in diameter that has a narrow pedicle; and (3) any but (1) and (2). The color can vary between normal skin color and brownish-red. Small, pedunculated soft fibromas can be removed with curved or serrated blade scissors, while larger skin tags may simply require excision. For small, soft fibromas, aluminum chloride applied prior to removal will decrease the amount of bleeding, which is usually minor anyway. Anesthesia prior to electrodesiccation is another option. Other methods of removal include cryotherapy and ligation with a suture or a copper wire; however, freezing of the surrounding skin during liquid nitrogen cryotherapy may result in dyschromic lesions. Taking hold of the acrochordon with forceps and applying cryotherapy to the forceps may provide superior results.

Keloid and hypertrophic scars

These scars are caused by the hyperproduction of collagen due to abnormal and prolonged cutaneous wound healing. It has been suggested that mechanical forces such as skin-stretching tension and mechanotransduction signaling pathways are associated with their generation and growth.⁵⁷ The differential diagnosis of keloids (Fig. 28.40) and hypertrophic scars (Fig.

Fig. 28.40 Typical keloids on the anterior chest of an Asian patient.

28.41) remains difficult; indeed, it is possible that they are manifestations of a fibroproliferative disorder of the skin⁵⁸ that expresses a continuum of features. Nevertheless, for simplicity in clinical situations, the terms “hypertrophic scars” and “keloids” can still be used: hypertrophic scars are considered to be those that improve naturally and gradually, although the full maturation process may take up to 2–5 years, whereas keloids are considered to be those that rarely resolve naturally. To prevent the development of these scars and to treat them, multimodal therapy²¹ that includes steroid ointment/tape/injection, taping fixation, silicone gel sheeting, surgery, radiation,⁵⁹ cryotherapy, laser, and 5-FU is recommended.

Lipoma

Lipoma is the most common of the mesenchymal soft-tissue tumors (Figs. 28.42 & 28.43). There are many subtypes,

Fig. 28.41 Typical hypertrophic scars on the thigh of an Asian patient.

Fig. 28.42 Lipoma on the nape (A) and the lesion after excision (B).

Fig. 28.43 Lipoma on the face.

including lipoblastoma, angiolipoma, spindle cell lipoma, pleomorphic lipoma, and hibernoma. It was shown recently that these adipocellular tumors are characterized by specific chromosome and gene abnormalities and that these abnormalities can be used for diagnosis. Lipomas can be classified according to their location into entities such as intramuscular and intermuscular lipoma. Systemic lipoma is termed lipomatosis (Fig. 28.44). Diffuse lipomatosis sometimes affects the limbs, head and neck, and intestinal tract. Lipomatosis on the finger results in megadactyly. Multiple symmetric

lipomatosis⁶⁰ mainly occurs on the upper body (Fig. 28.45). Steroid-induced lipomatosis can be a side effect of corticosteroid administration. A rapidly growing lipoma should be examined carefully to eliminate the possibility that it is actually a liposarcoma. Complete surgical excision with the capsule is advocated to prevent local recurrence.

Leiomyoma

Cutaneous or subcutaneous leiomyoma is a tumor that is derived from smooth muscles in the skin, including the arrector muscle of hair and vascular smooth muscle.⁶¹ These tumors are localized and are associated with pain. Leiomyomas can be categorized into four types: (1) multiple piloleiomyoma; (2) solitary piloleiomyoma; (3) angioleiomyoma; and (4) genital leiomyoma. Angioleiomyomas and genital leiomyomas usually occur as solitary lesions. In contrast, piloleiomyomas may be solitary or multiple; in the latter case, there may be thousands of lesions. This is because the arrector pili muscle from which piloleiomyomas originate has multiple points of insertion, such as those located proximal to the hair follicle, those located distal to the multiple attachment points within the papillary and reticular dermis, and those located in the basement membrane. Piloleiomyomas can emerge from each of these insertion points, thus occurring as multiple

Fig. 28.44 Multiple lipomatosis (A) and the lesions after excision (B).

Fig. 28.45 Multiple symmetric lipomatosis.

tumors. Angioleiomyoma often occurs on the distal area of the limbs, especially under the knee in women. In contrast, angiolipoma commonly occurs on the head in men and is often not associated with pain. Surgical excision or ablation of the leiomyoma may be helpful for some symptomatic individuals.

Rhabdomyoma

Rhabdomyoma is a benign tumor of striated muscle. It is most commonly associated with the heart and tongue but can also occasionally occur as a superficial mesenchymal tumor. There are adult, fetal, and genital types. The adult-onset type often occurs on the head and neck area, whereas the fetal type often occurs on the postauricular area of children under the age of 3 years. Patients with adult rhabdomyoma should have surgical resection of head and neck lesions, especially those lesions that compress or displace the tongue, or protrude and partially obstruct the pharynx or larynx. Fetal rhabdomyomas are usually located in the subcutaneous tissues.⁶² In most instances, they can be excised without much difficulty. Local excision is the treatment of choice for genital rhabdomyomas.

Osteochondrogenic tumors

Chondromas and osteochondromas often occur in adults on the hand and foot. Osteochondromas are sometimes associated with calcification. Osteomas are composed of mature

bone but can be considered to be reactive outgrowths. Osteoma cutis⁶³ refers to the presence of bone within the skin in the absence of a pre-existing or associated lesion, as opposed to secondary types of cutaneous ossification that are the result of metaplastic reactions to inflammation, trauma, and neoplastic processes. Osteoma cutis can be removed by excision or laser resurfacing that ablates the overlying skin. Myositis ossificans, panniculitis ossificans, and fibrodysplasia ossificans progressiva are also reactive ossifications. Exostosis is also considered to be a reactive osteochondrogenic disorder (Fig. 28.46). This often occurs on the cranial and subungual regions. Exostosis can be removed easily by a chisel and hammer, and its recurrence is rare.

Accessory auricle (also known as nevus cartilagineus)

This congenital nevus arises from the area between the tragus and the lateral neck (Fig. 28.47). Nevi that are near the ear are largely composed of cartilage, while nevi that are distant from the ear are mainly composed of hair follicles. Multiple accessory auricles⁶⁴ are sometimes associated with hemifacial microsomia. Surgical removal may be possible. If so, sufficient skin and cartilage should be removed so that flat and linear scars are the result rather than a dog-ear deformity.

Granuloma

Granulomas can be broadly classified as infectious (Fig. 28.48) and noninfectious. Almost all noninfectious granulomas are foreign-body granulomas; some of these are associated with a type IV allergy. There are a number of causes of foreign-body granuloma. These can be divided into endogenous causes such as uric acid salt, cholesterol, and sebum production, and exogenous causes such as materials injected for aesthetic surgery⁶⁵ (Fig. 28.49), vaccines, surgical sutures, and materials implanted by trauma (Fig. 28.50). Small pyogenic granulomas (telangiectatic granulomas) and foreign-body granulomas can be removed by surgery, but this may not be possible for large and multiple granulomas. In this case, systemic or local corticosteroid administration to reduce inflammation should be considered.

Fig. 28.46 Exostosis on the frontal bone (A) and the excised specimen (B).

Fig. 28.47 Accessory auricle.

Fig. 28.48 Pyogenic granuloma on the back.

Fig. 28.49 Foreign-body granuloma caused by a nasal implant.

Glomus tumor

Glomus tumors arise from the arterial portion of the glomus body, or the Sucquet–Hoyer canal, which is an arteriovenous anastomosis in the dermis that participates in temperature regulation. Patients with solitary glomus tumors usually have paroxysmal pain that can be severe and exacerbated by pressure or temperature changes, especially cold. Multiple glomus tumors can also be painful but are less common; the pain is also usually not severe. Two features that are useful for diagnosing glomus tumors, particularly solitary painful glomus tumors (especially those under a nail), are the Hildreth sign, which is the disappearance of pain after a tourniquet is placed on the proximal arm, and the Love test, where pain is elicited by pressing the skin overlying the tumor with the tip of a pencil. The treatment of choice for solitary glomus tumors is surgical excision. For multiple glomus tumors,⁶⁶ excision may be more difficult because of their poor circumscription and the large number of lesions. In this case, excision should be limited to symptomatic lesions.

Capillary malformation

Hemangioma simplex

This is the result of the abnormal development or differentiation of capillary vessels in the dermis.⁶⁷ According to its location, it can be classified into three types: (1) portwine stain

(face, limbs, and upper body) (Figs. 28.51 & 28.52); (2) salmon patch (medial forehead, glabella, nasal tip, and upper lip); and (3) nevus Unna (nape). Portwine stains are sometimes associated with Sturge–Weber syndrome (face) and Klippel–Trenaunay syndrome (limb). Patients with solitary hemangioma simplex, regardless of whether they have these syndromes, should be subjected to brain examinations. Of the three types, only the salmon patch can disappear within a year after birth. A dye laser or Nd:YAG laser can be used to treat these lesions.

Strawberry hemangioma

This tumor is derived from the endothelial cells of capillary vessels in the skin. It arises around 3–4 weeks after birth and its growth peaks at 6–7 months of age (Figs. 28.53 & 28.54). After this growth period, the volume rarely decreases naturally, although the color can become less livid spontaneously. Consequently, laser treatments with, for example, dye or Nd:YAG lasers should be performed at an early stage to prevent the capillaries from proliferating further.⁶⁸ On a case-by-case basis, surgical excision, steroid injection, and compression therapy may also be suitable.

Venous malformation

A representative type of venous malformation is a cavernous hemangioma, which is a blood-storing lesion with a low blood flow (Fig. 28.55). Histology shows the absence of

Fig. 28.50 Foreign-body granuloma caused by the implantation of a large wood splinter (A) and view of the patient just after surgery (B).

Fig. 28.51 Portwine stain on the face of an infant.

Fig. 28.52 Portwine stain on the face of an adult.

endothelial cell proliferation. It is seen in Klippel–Trenaunay syndrome, which is characterized by various malformations, including capillary malformation and bony and soft-tissue hypertrophy. Venous malformation is best treated with sclerosing therapy, where sclerosing agents like absolute ethanol, polidocanol, sodium tetradecyl sulfate, or ethanolamine oleate are injected into the lesion under ultrasound or digital subtraction angiography guidance.⁶⁹

Arteriovenous fistula and arteriovenous malformation (AVM)

Arteriovenous fistula and AVM are high-flow pulsating lesions with an arteriovenous shunt; they are either acquired because of trauma or are congenital (Fig. 28.56). CDI is useful for detecting the blood flow in the tumor. Patients with Parkes–Weber syndrome who have a huge limb AVM sometimes exhibit congestive heart failure. The Schobinger classification allows AVMs to be classified into four clinical stages: (I) quiescence; (II) expansion; (III) destruction; and (IV) decompensation. Patients with heart failure are considered to have stage IV AVMs. Surgical removal is the first choice of treatment but is often hampered by the diffuse distribution of

the vessels and the specific anatomy in the affected region (e.g., the local presence of a facial nerve). Incomplete resection results in the rapid regrowth of the remaining lesion. In cases where surgical removal is difficult, embolosclecting therapy can be used as a palliative therapy.⁷⁰

Lymphatic malformation

There are two main types of lymphatic malformation: lymphangioma and cystic hygroma. Clinically, lymphatic malformation can be classified into macrocyst (cystic hygroma and lymphangioma cystoides), microcyst (lymphangioma simplex), and combined (lymphangioma cavernous) types. The microcysts can be removed surgically, while the macrocysts and combined types should be treated by surgery or sclerotherapy using OK-432⁷¹ or absolute ethanol on a case-by-case basis.

Fig. 28.58 Actinic keratosis on the cheek of an elderly patient.

Fig. 28.57 Mucous cyst of the oral mucosa.

Fig. 28.59 Squamous cell carcinoma on the cheek of an elderly patient.

Others

There are many other benign mesenchymal-origin tumors. These include giant cell tumor, histiocytoma, reticulohistiocytoma, fibroxanthoma, desmoid tumor, mucous cyst of the oral mucosa (Fig. 28.57), cutaneous myxoma, Langerhans cell histiocytosis, Kimura disease, plasmacytosis, and mastocytosis.

Malignant cutaneous and soft-tissue tumors

Malignant epithelial-origin tumors

Actinic keratosis

Actinic keratosis is an intraepidermal early-stage SCC caused by long-term exposure to ultraviolet light (Fig. 28.58). It is mostly seen in the elderly, especially fair-skinned people who have been highly exposed to the sun. The areas that bear the lesions are those that have been most exposed. Over time, actinic keratoses develop into invasive SCC. They are epidermal lesions that are characterized by aggregates of atypical, pleomorphic keratinocytes at the basal layer that may extend upwards to involve the granular and cornified layers. Cutaneous horns⁷² sometimes occur in association with a

hyperkeratotic actinic keratosis. Surgical removal is recommended but cryosurgery, CO₂ lasers, 5-FU ointment, and chemical peeling may also be useful for selected cases.

Bowen's disease

Bowen's disease is an intraepidermal carcinoma since it is a malignant tumor of keratinocytes. It can progress to invasive SCC. If the invasion is deep, it is termed Bowen's carcinoma; this carcinoma can metastasize. The diagnosis of Bowen's disease is often delayed because the lesion is asymptomatic and early skin changes may be subtle and overlap with the clinical features of many conditions, including tinea corporis, nummular eczema, seborrheic keratosis, Paget's disease, superficial BCC, actinic keratosis, and psoriasis. A classic feature of the clinical history is the presentation of a nonsteroid-responsive dermatosis. Surgical removal is recommended but cryosurgery, CO₂ lasers, 5-FU ointment, and imiquimod 5% cream⁷³ may also be suitable for selected cases.

Squamous cell carcinoma

SCC is a common cutaneous malignancy that often presents as an elevated, indurated lesion with varying degrees of ulceration and crusting (Fig. 28.59). SCC can arise on any site but is most common in damaged skin such as actinically damaged skin, postburn scars (Marjolin's ulcer), traumatic

Fig. 28.60 Squamous cell carcinoma on the sole that has arisen from traumatic scars.

Fig. 28.61 Advanced squamous cell carcinoma on the face that shows necrosis and infection.

Fig. 28.62 Basal cell carcinoma on the scalp.

scars (Fig. 28.60), stasis ulcers, chronic radiation dermatitis, lupus erythematosus lesions, lichen planus on the oral mucosa, and human papillomavirus infection lesions. One type of SCC is verrucous carcinoma. Since SCC can resemble BCC, it is important to make a differential diagnosis. One notable characteristic of SCC is the bad smell caused by the macerated keratin and bacterially infected necrotic tissues (Fig. 28.61). SCC should be removed by surgery. Mohs micrographic surgery⁷⁴ is frequently used to remove SCCs. Radiotherapy given as external-beam radiotherapy or as brachytherapy (internal radiotherapy) can also be used.

Basal cell carcinoma

BCC is the most common type of skin cancer (Fig. 28.62). It rarely metastasizes and kills, but is still considered malignant

because it can invade surrounding tissues and cause significant destruction and disfigurement. It most commonly affects the head and neck, and cosmetic disfigurement is not uncommon. It can be classified into 10 types⁷⁵ (Box 28.5). It should be removed by surgery. Mohs micrographic surgery is frequently utilized. However, for selected cases of superficial BCC, CO₂ lasers or cryosurgery can be used.

Malignant appendage-origin tumors

Sebaceous carcinoma

Meibomian gland carcinoma (Fig. 28.63), Zeis gland carcinoma, and Montgomery's gland carcinoma are all sebaceous carcinomas. These carcinomas often exhibit erosion and ulceration. A wide excision with a normal skin margin exceeding 5 mm is recommended. Lymph node dissection should be considered in T4 cases because of the high rate of lymph node metastasis associated with sebaceous carcinomas. Chemotherapy and radiation therapy may also be useful.⁷⁶

Trichilemmal carcinoma

The outer hair root sheath consists of cells with clear vacuolated cytoplasm due to the presence of abundant glycogen. Trichilemmal carcinomas are malignant tumors of these cells. They include malignant trichilemmoma, malignant pilomatricoma, and malignant proliferating trichilemmal cyst (Fig. 28.64). The latter is thought to be derived from proliferating trichilemmal cyst,³² while malignant pilomatricoma is believed to be derived from pilomatricoma. Clinically, these tumors present as pale tan or reddish papules, indurated plaques, or nodules. Wide excision should be performed as a radical therapy.

Sweat gland carcinoma

There are many types of eccrine and apocrine carcinomas. These malignant primary cutaneous tumors exhibit glandular and/or ductal features that are thought to reflect their origin

Fig. 28.63 Meibomian gland carcinoma on the upper eyelid.

as eccrine or apocrine ducts and/or glands. The diagnosis of sweat gland carcinoma requires that the tumor shows sweat gland features, as shown by extracellular ductal or intracytoplasmic lumen formation. This can be indicated by resistance to diastase, staining with periodic acid–Schiff stain, and immunohistochemical positivity for epithelial membrane antigen and carcinoembryonic antigen. The presence of S100 protein may also indicate sweat gland differentiation. Conventional surgical excision has been associated with high recurrence rates but Mohs micrographic surgery is helpful.⁷⁷ These carcinomas should be treated according to the guidelines for SCC.

Extramammary Paget's disease

Paget's disease is an adenocarcinoma that is limited to the epidermis. Since mammary Paget's disease is sometimes associated with invasive breast cancer, it can be considered as an intraepidermal proliferating breast carcinoma. In contrast, EMPD is only occasionally associated with an underlying invasive malignancy. It is usually found in the vulva, penis, and axilla. Since its invasive speed is relatively high, it can be difficult to detect early, especially if the lesion has been treated as eczema. Mohs micrographic surgery⁷⁸ or mapping biopsy is helpful for determining the normal skin margin for wide

Fig. 28.64 Malignant trichilemmal cyst.

excision (**Fig. 28.65**). Sentinel lymph node biopsy is also useful for deciding whether to remove the lymph nodes.

Merkel cell carcinoma

Merkel cell carcinoma is a rare and highly aggressive cancer where malignant cancer cells develop on or just beneath the skin and in hair follicles (**Fig. 28.66**). The majority of Merkel cell carcinomas appear to be caused by the newly discovered Merkel cell polyomavirus. It occurs most often on the face, head, and neck, and usually appears as firm and painless nodules or tumors. A normal skin margin of 1–2 cm is needed for wide excision. Moreover, since this tumor tends to metastasize to lymph nodes, lymph node dissection and adjuvant radiation therapy may have to be implemented.⁷⁹ Distant metastasis cases should also receive chemotherapy.⁷⁹

Malignant mesenchymal-origin tumors

Dermatofibrosarcoma protuberans (DFSP)

DFSP is also called giant cell fibroblastoma. Over 90% of DFSP tumors have the chromosomal translocation t(17;22) that fuses the collagen gene COL1A1 with the platelet-derived growth factor gene. Typically, DFSP occurs as multiple or solitary tumors that have a red color, hemispherical elevation, and papillary vessels on the surface (**Fig. 28.67**). They have a keloidal appearance, which has sometimes led to

Fig. 28.65 Mapping biopsy for extramammary Paget's disease.

Fig. 28.69 Liposarcoma on the thigh.

misdiagnosis and treatment with corticosteroids. They metastasize rarely, but distant metastasis to the lung can result from local recurrence. Radical resection should include a normal skin margin of 5 cm. Mohs micrographic surgery with continuous histological margin control is needed to reduce local recurrence rates.⁸⁰ Adjuvant chemotherapy and radiation therapy may be useful.

Pleomorphic undifferentiated sarcoma (PUS)

There are four types of malignant fibrous histiocytoma (which is more recently being classified as pleomorphic undifferentiated sarcoma⁸¹): (1) storiform-pleomorphic type; (2) myxoid type; (3) giant cell type; and (4) inflammatory type. Moreover, atypical fibroxanthoma is considered to be a superficial type (Fig. 28.68). Despite being called histiocytomas, these tumors are not believed to be derived from histiocytes. In fact, it is currently being argued on the basis of immunohistochemistry and electron microscopic observations⁸² that most of the storiform-pleomorphic type should be reclassified as liposarcomas, leiomyosarcomas, or rhabdomyosarcomas. Radical therapy involving wide excision is needed. Adjuvant chemotherapy and radiation therapy may also be useful.

Liposarcoma

Liposarcoma is derived from the fat cells in deep soft tissues such inside the thigh or the retroperitoneum (Fig. 28.69). They are generally large and bulky tumors with multiple smaller satellites located outside the main tumor. Diagnosis requires the detection of lipoblasts, which usually have an abundant, clear, multivacuolated cytoplasm and an acentric, darkly staining, vacuole-compressed nucleus. Dedifferentiated liposarcomas exhibit a dedifferentiated area in the tumor that sometimes results in osseous metaplasia.⁸³ Radical therapy involving wide excision is needed. Adjuvant chemotherapy and radiation therapy may be useful.

Leiomyosarcoma

This rare malignancy mainly occurs on the limbs of middle-aged and older patients (Fig. 28.70). It can be very unpredictable as it can remain dormant for long periods of time and recur after years. It is generally not very responsive to chemotherapy or radiation. However, neoadjuvant or adjuvant chemotherapies,⁸⁴ or radiation, are recommended.

Rhabdomyosarcoma

Rhabdomyosarcoma is thought to arise from skeletal muscle progenitors and occurs in many anatomic locations.

Fig. 28.70 Leiomyosarcoma on the face.

Fig. 28.71 Computed tomography of an osteosarcoma on the frontal bone.

Sometimes it is found attached to muscle tissue or wrapped around intestines. Mostly it occurs in areas that naturally lack skeletal muscle, such as the head, neck, and genitourinary tract. Its three most common forms are embryonal rhabdomyosarcoma, alveolar rhabdomyosarcoma, and pleomorphic rhabdomyosarcoma. Embryonal rhabdomyosarcoma is more common in younger children, where the cancer cells resemble those of a typical 6–8-week embryo. Alveolar rhabdomyosarcoma occurs more commonly in older children and teenagers, and the cells resemble those of a typical 10–12-week embryo. Pleomorphic rhabdomyosarcoma is a rare sarcoma that occurs most often in older patients. Radical therapy involving wide excision is needed. There is also evidence that rhabdomyosarcomas are the target of host immune responses.⁸⁵

Osteosarcoma

This aggressive cancerous neoplasm arises from primitive transformed cells of mesenchymal origin that exhibit osteoblastic differentiation and produce malignant osteoids (Fig. 28.71). Complete radical surgical *en bloc* resection is the treatment of choice.⁸⁶ Some recent studies have suggested that osteoclast inhibitors such as alendronate and pamidronate may improve the quality of life by reducing osteolysis, which decreases the pain as well as the risk of pathological fractures.

Chondrosarcoma

At presentation, nearly all chondrosarcoma patients appear to be in good health as this form of cancer usually does not affect the whole body. Indeed, the patients are generally not aware of the growing tumor until there is a noticeable lump or pain. An earlier diagnosis is generally accidental, such as when a patient undergoes testing for another problem. Occasionally, the first symptom will be a broken bone at the cancerous site. Therefore, broken bones due to mild trauma warrant further investigation, even though there are many conditions that can lead to weak bones and this form of cancer is not a common cause of such breaks. Chemotherapy or traditional radiotherapy is not very effective for most chondrosarcomas, although proton beam radiation therapy is showing promise with regard to local tumor control.⁸⁷ Complete surgical ablation is the most effective treatment but can be difficult to achieve. Proton beam radiation can facilitate the surgical removal of chondrosarcomas in awkward locations.

Angiosarcoma

Angiosarcoma is the common name for malignant neoplasms of endothelial cells (Fig. 28.72) but it is replaced with the terms

Fig. 28.72 Angiosarcoma on the axilla.

lymphangiosarcoma and hemangiosarcoma when more clinical precision is required. Haemangiosarcomas and lymphangiosarcomas of the skin are not uncommon. Given the location of angiosarcomas, metastasis to distant sites occurs often. Surgery, radiation therapy, chemotherapy, and immunotherapy using interleukin-2⁸⁸ should be used, but the prognosis of these tumors is poor. However, the prognosis of neoplasia of superficial vessel tissues such as those in the skin is generally better because the risk of malignancy is lower; moreover, these tumors are generally more accessible to treatment.

Kaposi's sarcoma

Kaposi's sarcoma is caused by the Kaposi's sarcoma-associated herpesvirus (KSHV), also known as human herpesvirus 8. It became widely known after its frequent appearance in acquired immune deficiency syndrome patients was noted in the 1980s. Although the viral cause of this cancer was discovered in 1994, this causal link remains poorly understood by the general populace, including by the groups that are at particular risk of contracting KSHV. Kaposi's sarcoma lesions present as red, purple, brown, or black nodules or blotches that are usually papular (i.e., palpable or raised). They are typically found on the skin but can often spread elsewhere, especially to the mouth, gastrointestinal tract, and respiratory tract. Their growth can range from very slow to explosively fast, and they are associated with significant mortality and morbidity. Radiation therapy, cryotherapy, and chemotherapy may be useful. Surgery is not the primary choice of treatment, although it may be useful as supportive therapy. Highly active antiretroviral therapy should be combined with these therapies.⁸⁹

Others

Other malignant mesenchymal-origin tumors include epithelioid sarcoma, synovial sarcoma, extraskelletal Ewing's sarcoma, histiocytic sarcoma, and Langerhans cell sarcoma. In general, treatment consists of induction chemotherapy, wide surgical excision, and then maintenance chemotherapy. Multi-agent chemotherapy has improved survival rates.

Melanoma

Stephan Ariyan and Aaron Berger

SYNOPSIS

- The definitive diagnosis of melanoma is based on histologic analysis. Clinical features suggestive of malignancy include: asymmetry, border irregularity, color changes, diameter $> \frac{1}{4}$ inch, and evolving changes; the ABCDE criteria.
- The four major histopathologic subtypes of melanoma are: lentigo maligna, superficial spreading, nodular, and acral lentiginous. Desmoplastic melanoma is a less common subtype of melanoma that lacks pigment and may demonstrate perineural invasion.
- Initial work up of the pigmented lesion should include excisional biopsy with a 1–2-mm margin of normal-appearing skin. If functional or cosmetic concerns prohibit removal of the entire lesion, incisional or punch biopsy may be performed.
- Histologic evaluation of the primary lesion must include: Breslow depth in millimeters, presence/absence of ulceration, mitotic rate per mm^2 , peripheral and deep margin status, and Clark level (especially for lesions ≤ 1 mm in depth).
- Recommended excision margins are determined by Breslow depth. *In situ* melanoma requires a 0.5-cm margin of normal-appearing skin. For invasive melanoma, a 1-cm margin is recommended for lesions ≤ 1 mm in depth, a 1–2-cm margin is recommended for lesions 1.01–2.0 mm in depth (dependent upon functional/cosmetic concerns), and a margin of at least 2.0 cm is recommended for lesions > 2.0 mm in depth.
- Subungual melanoma of the hand should be resected at the distal interphalangeal joint to preserve function.
- Sentinel lymph node biopsy (SLNB) is offered to patients with melanomas > 1 mm in thickness, and patients with thin melanomas (≤ 1 mm thick) that demonstrate high-risk features, including ulceration and/or high mitotic rate. The likelihood of detecting metastatic deposits in an SLNB increases with the thickness of the primary lesion.
- For patients with stage I and II disease, chest X-ray and liver function tests compose the recommended workup. Patients with regional (stage III) or systemic metastases (stage IV) should undergo a comprehensive staging workup that may include CT scans with PET imaging.
- Serum LDH (lactate dehydrogenase) is used in the AJCC staging system as it portends a worse prognosis in patients with metastatic disease.

- Patients with high-risk primary tumors or metastatic disease should be considered for adjuvant treatment with interferon-alfa or enrollment in a clinical trial.

Introduction

Few diseases are as fascinating and as troublesome to physicians as malignant melanoma, and perhaps no other disease elicits as much fear in the patient as does this diagnosis. Although it accounts for only 4% of all malignant neoplasms, its very diagnosis suggests to some patients an aggressive, rapid progression to death. The name alone may leave some patients with a sense of hopelessness that is often unjustified. Despite some reported descriptions of rapid spread, the natural history of melanoma and its overall cure rate of 80% compare favorably with those of cancers of the breast, colon, rectum, and oropharynx and are far better than for cancer of the lung.

Epidemiologic studies demonstrate that the incidence of melanoma has been increasing faster than that of any other cancer in the United States.¹ It is estimated that there were 76100 new diagnoses of melanoma and 9710 deaths in the United States in 2014.² Melanoma incidence rates doubled from 1982 to 2011.³ An individual dying from melanoma loses an average of 20.4 years of potential life.⁴

Our understanding of melanoma continues to improve, and we can now differentiate low-risk from high-risk patients on the basis of multifactorial analyses from several series of large numbers of patients. However, despite our best attempts to understand the molecular basis of this disease, limited success has been demonstrated in terms of new medical treatments, and successful treatment of this disease relies heavily upon the surgeon.

Historical perspective

Although Hippocrates is credited with the first reported observation of what appears to be a melanoma, Handley⁵ attributes the first clinical case of malignant melanoma reported in England to Dr. William Norris. In 1820, Norris felt compelled to report this case because of the rapid spread of the tumor, which led to his patient's death. He reported that at the autopsy, every organ except the spleen and the bladder was riddled with "black specks".⁶ The patient's father had died of similar disease, and the patient's brothers and his children had "many moles on various parts of their bodies".

Handley had never himself treated a patient with a melanoma, but he made considerable observations after performing an autopsy on a 34-year-old woman who had died of disseminated metastatic melanoma. He was interested in the mechanisms of spread of melanoma. Halsted had already described the spread of breast cancer along the lymphatics surrounding the primary tumor.^{7,8} In his two Hunterian lectures, Handley proposed that the primary spread of melanoma was through the lymphatics and not by blood vessels. In his first lecture, he described his autopsy findings; the 34-year-old woman previously had a primary melanoma excised from her right foot over the Achilles tendon. At autopsy, Handley observed a large collection of tumor growths in the right groin and virtually every part of the body except the entire left leg (Fig. 29.1). Arguing incorrectly that every organ would have been involved if tumor spread were hematogenous, he stated that sparing of the spleen, bladder, stomach, and left leg could be explained by "lymphatic permeation". Although Handley did not discount the concept of hematogenous spread, he believed that early dissemination was by lymphatics and that invasion of the blood stream occurred later "either by local infiltration of veins from concomitant permeated lymphatics, or by malignant cells carried into the blood along the thoracic duct from invaded lymphatic glands".⁵

In his second lecture, Handley proposed that lymphatics were amenable to surgical removal with the primary melanoma. He based his treatment recommendations on histologic examination not of the primary site but of the regional groin recurrence. Indeed, Handley had confessed that "no opportunity of investigating the spread of permeation round a primary focus of melanotic growth has fallen to me".⁹

Nevertheless, because the site of the groin recurrence had shown "permeation spreading centrifugally in the lymphatic plexus of the deep fascia and invading skin and muscle secondarily over a smaller area", he advocated a wide radical resection for a primary melanoma (Fig. 29.2): "A circular incision should be made through the skin round the tumour ... situated as a rule about an inch from the edge of the tumour, should be just deep enough to expose the subcutaneous fat...

Fig. 29.1 Autopsy findings of patient with melanoma of right ankle spreading in a centripetal manner to right groin and remainder of body while sparing the left leg. (Redrawn from Handley WS. *The pathology of melanotic growths in relation to their operative treatment. Lecture I. Lancet. 1907;1:927.*)

The skin with a thin attached layer of subcutaneous fat is now to be separated from the deeper structures for about two inches in all directions round the skin incision.... Finally, the whole mass with the growth at its centre is removed by scooping out with a knife a circular area of the muscle immediately subjacent to the growth."⁹

This approach presented a minimal excision of 2.5 cm of skin and 5 cm of subcutaneous tissue surrounding the melanoma, down to and including the muscle fascia, as well as incorporating a portion of the underlying muscle. Therefore, it is this report by Handley, in which he recommended a 5-cm margin of skin and soft tissues around a melanoma, that appears to be the first such proposal for a wide margin of resection.

Fig. 29.2 Handley recommended removal of melanoma (a) together with 1 inch (f) of skin (b) and 2 inches (g) of underlying subcutaneous fat (c), muscle fascia (d), and muscle (e). h, skin incision. (Redrawn from Handley WS. *The pathology of melanotic growths in relation to their operative treatment. Lecture I. Lancet. 1907;1:927.*)

Handley believed that the regional lymph nodes also should be removed as part of the first operation. Furthermore, he advised that the excision of these glands be complete, “that is to say, a larger circular area of the surrounding deep fascia must be exposed, dissected up from its circumference towards the infected glands, and removed in one piece with them”. He then reported the treatment of a melanoma of the thigh by a senior colleague, A.P. Gould, by resection of the primary tumor and femoral nodes in this manner, but the patient had iliac node recurrence within 2 months.

In the year after Handley’s lecture, Pringle¹⁰ described three patients with melanoma whom he treated during the previous 10 years. However, Pringle further advocated removal of all subcutaneous tissue, including the lymphatics, between the primary site and the regional nodes together with the specimen. This was the first paper to describe the technique of an in-continuity dissection. He reported that one of his patients – a young woman who was alive 9 years after surgery at the time of the report – had moved to Canada, married, and had children. Pringle concluded in his report that “all that is removed should be in one continuous strip as far as possible”.

These early papers established the trends toward aggressive treatment of primary melanoma by wide excision of the tumor together with the underlying muscle and its fascia and by in-continuity lymph node dissection in an effort to achieve better cures. As Handley stated in his Hunterian lecture: “Nowadays the improved operation for breast cancer produces prolonged or permanent immunity in about 50 percent of cases. And upon the evidence I have laid before you I venture to predict that the application of more thorough and scientific methods to the surgery of cutaneous melanomata will produce a corresponding, though perhaps a smaller, improvement in the results of operation.”⁹

However, the methods of treating melanoma changed very little during the first half of the 20th century. The various reports of cure rates after aggressive surgical treatment of melanoma remained the same: a better prognosis if the patient did not have clinically palpable nodes (80% 5-year cure rate for stage I disease) than if the nodes were palpable (40% cure rate for stage II disease).¹¹

Subsequently, surgeons gained some information on prognostic factors of this tumor. Within each clinical stage, the prognosis is improved by the pathologic findings of no evidence of metastatic tumor cells on microscopic examination of the removed lymph nodes. However, the advantage of in-continuity removal of all tissues between the primary site

and the regional lymph nodes, as advocated by Pringle¹⁰ and as widely employed for decades, was challenged by Goldsmith *et al.*¹¹ who demonstrated no difference between this technique and that of discontinuous dissection of the primary tumor and the lymph nodes (Table 29.1). They, too, found no difference between immediate and delayed lymphadenectomy.

Finally, the issue regarding excision of underlying muscle and fascia was evaluated and resolved. Olsen¹² reviewed a series of 67 patients treated for melanoma in Denmark between 1949 and 1957. She found a 45% incidence of subsequent regional nodal metastases among the 31 patients who had the fascia removed during excision of the primary tumor and a 14% incidence of metastases among the 36 patients in whom this fascia was left intact. Because the patients who underwent a fasciectomy may have had more aggressive tumors, Olsen reviewed the next 51 patients treated from 1958 to 1961 who did not undergo excision of the fascia and observed only a 10% incidence of regional metastases. Kenady *et al.*¹³ reviewed their data of 202 patients treated at the M.D. Anderson Hospital, Houston, from 1961 to 1974 and found that local recurrence, regional nodal recurrence, distant metastases, and survival were not statistically different between the 107 patients who had the fascia excised and the 95 patients who did not. There appears to be no indication for removal of underlying muscle fascia unless the fascia becomes involved by contiguous tumor growth. In fact, the risk of lymphedema may be decreased by preserving the muscle fascia. In a series of 209 consecutive patients, 119 undergoing complete axillary lymphadenectomy, permanent upper extremity lymphedema occurred in 5% of the patients; and in 93 patients undergoing ilioinguinofemoral lymphadenectomy, permanent lower extremity edema occurred in 14% of the patients.¹⁴

Table 29.1 Outcome based on interval of timing of node dissection

Clinical stage	No. of patients	Nodal dissection	5-year cure rate	
			Simultaneous	Delayed
I	296	In continuity	63 (76%)	165 (78%)
		Discontinuous	15 (75%)	53 (75%)
II	435	In continuity	53 (42%)	167 (42%)
		Discontinuous	20 (35%)	195 (41%)

(Modified from Goldsmith HS, Shah JP, Kim DH. Prognostic significance of lymph node dissection in the treatment of malignant melanoma. *Cancer*. 1970;26:606.)

Fig. 29.3 (A) Junctional nevus is flat, smooth, and nonpalpable. (B) Compound nevus is developing into mature, thicker intradermal nevus in center within a flat junctional nevus in periphery. (C) Intradermal nevus is mature mole with elevation of the surface elements due to thickening of the layer of nevus cells. (D) Blue nevus presents with melanin deposits deep in the dermis reflecting the blue wavelength of light.

Clinical evaluation

Clinical diagnosis

The definitive diagnosis is not made until the specimen is examined histologically. Therefore, a review of the various pigmented lesions is essential for making a differential diagnosis.

All infants are born with nevi, but the lesions are usually not apparent at birth because they do not produce pigment. During the following few weeks or months, melanocytes produce pigment as a response to circulating hormones. As the nevi develop, they undergo maturation, which leads to the classification of the following various forms.

Junctional nevus

Junctional nevi are small flat lesions that first appear after birth and are smooth, nonpalpable, and light to dark brown or black (Fig. 29.3A). They are called junctional because the nevus cells are located at the interface of the epidermis and dermis. As the person develops and matures, the nevus cells grow and push into the dermis to develop into the common adult intradermal nevus.

Compound nevus

As the nevus matures, the central portion pushes into the dermis, causing this central portion to elevate and appear thicker (Fig. 29.3B). This nevus is called compound because the central portion is intradermal and thick, whereas the periphery is still junctional and flat. Compound nevi often are seen during adolescence, and the changes in such moles may cause concern to the patient, family, or primary care physician.

Intradermal nevus

The intradermal nevus is the common adult mole of the face or trunk that is elevated because of the maturation and proliferation of the nevus in the dermis, which now pushes up the overlying epidermis (Fig. 29.3C). It may be light or dark, usually is elevated, and may be sessile or pedunculated.

Blue nevus

Most nevi appear brown or black because the melanin is superficial and absorbs light. When the nevus contains melanin that is located more deeply, blue wavelengths of light

pass through the less pigmented epidermis and are reflected back to the eye as a blue nevus (Fig. 29.3D).

Congenital nevus

Congenital nevi differ from others in that they already produce pigment at birth (Fig. 29.4A). There is some controversy about

Fig. 29.4 (A) Congenital nevus is a large flat pigmented mole that has produced pigmentation *in utero* and is present as a pigmented lesion on the day of birth. It may be hairy (as in this case) or not. (B) Invasive (1.4 mm) melanoma developed within a congenital nevus on the trunk of a 57-year-old male.

whether congenital nevi are precursors of melanoma. Kaplan's review¹⁵ of the literature reported the transformation to melanoma to occur in 2% to 42% of congenital nevi (Fig. 29.4B). In a retrospective study of 234 melanomas by Rhodes and Melski,¹⁶ some of the histologic features of congenital nevi were found among 8% of the melanoma specimens. A systematic review of all studies evaluating the risk of melanoma in congenital nevi was performed by Krengel.¹⁷ A total of 6571 patients with congenital nevi were followed for at least 3.4 years, and 46 patients (0.7%; range 0.05% to 10.7%) developed 49 melanomas. Of note, primary melanomas arose inside the nevi in 67% of cases. Using age-adjusted data from the Surveillance, Epidemiology and End Results (SEER) database, they calculated that patients with congenital nevi carry an approximately 465-fold increased relative risk of developing melanoma during childhood and adolescence. Patients with large congenital nevi (Fig. 29.5), greater than 40 cm in diameter, were associated with the highest risk of developing melanoma, as well as dying from melanoma.^{17,18} However, the true incidence of the development of melanoma within congenital nevi is difficult to determine as the number of patients in the general population who have congenital nevi but never consult a physician, or eventually undergo excision, is unknown.

On the basis of available information about the potential for malignant transformation, it is a good policy to remove congenital nevi if it can be done without much difficulty or disfigurement (see Fig. 29.5). Malignant transformation does not usually occur before adolescence, thus, if the lesion is to be excised, it should be done before adolescence. Because it is difficult to excise nevi from the skin of children under local anesthesia and general anesthesia is often necessary for children younger than 12 years, the risk of complications from general anesthesia should be weighed against the risk of malignant transformation before adolescence. On the other hand, patients may request removal of the lesion to improve their appearance. Despite concerns for appearance, some lesions cannot be completely removed because in doing so we may cause a greater deformity. These lesions may require staged excisions.

Atypical (dysplastic) nevus

The atypical nevus is a clinical diagnosis of a nevus with melanocytes involving the epidermis and dermis that have features suggestive of malignancy. Clinically, it is large (>6 mm), with a macular surface, irregular margin, and

Fig. 29.5 Staged excision. A large truncal congenital nevus (A) was excised from the central portion of the lesion (B) to reduce the size of the lesion to half after one operation (C). A second procedure a year later (D) removed the remainder of the lesion (E).

Fig. 29.6 Dysplastic nevus is a histologic confirmation of the clinical entity called atypical nevus. This is a large (>6 mm) flat mole of varying coloration.

variegated color. It may have a background of erythema (Fig. 29.6). These are benign lesions with histologic features that are abnormal. At various times, they have been called atypical nevi or dysplastic nevi. A National Institutes of Health Consensus Conference in 1992 recommended the descriptive term *atypical nevus* for the clinical diagnosis and the histologic term *dysplastic nevus* to describe the histologic degree of atypia and architectural disorder.¹⁹

To ensure accurate diagnosis, histologic examination of the lesion is required. Microscopically, the dysplastic nevus has melanocytic hyperplasia, with the melanocytes arranged as solitary units or small elongated nests oriented parallel to the long axes of the rete ridges. The melanocytes have nuclear atypia and abundant cytoplasm with a fine “dusty pattern” of melanin deposits.²⁰ Dysplastic nevi are often associated with atypical melanocytic hyperplasia, lymphocytic infiltration, and some evidence of regression. As such, patients with these lesions are believed to be at greater risk for transformation to melanomas.

Atypical (dysplastic) nevus syndrome

Studies at several institutions have found atypical nevi in association with melanoma that has no familial pattern. At the University of Pennsylvania, Elder *et al.*²¹ first described this as the dysplastic nevus syndrome in their 1980 report. In the same year, the Yale Melanoma Unit visited the Sydney Melanoma Unit in Australia and documented the presence of atypical nevi in 37% of 296 patients with melanoma who had no known family history.²² Similar atypical nevi were discovered in only 7% of a control population of male prison inmates without any history of melanoma.²² Clinically, these moles were large and resembled the dysplastic nevi of familial melanoma. Biopsies showed a 90% correlation between the histologic diagnosis of dysplastic nevi and the clinical appearance of these atypical moles. The tendency to develop atypical nevi is presumed to have a genetic basis, and the diagnosis of “atypical nevus syndrome” has been applied to patients with a range of phenotypic expressions,²³ including just the

presence of multiple atypical nevi and no personal or family history of melanoma, to the familial atypical multiple mole and melanoma syndrome.²⁴

B-K mole syndrome

Some prospective studies have shown that melanoma may be associated with a familial distribution in 10% to 11% of cases.²⁵ These familial melanomas tend to appear earlier and are distributed among dysplastic nevi over the body, with an excess over the trunk and a deficit over the upper extremities. Clark *et al.*²⁶ and Reimer *et al.*²⁷ suggested the role of atypical moles and dysplastic nevi in the development of hereditary melanoma when they described these moles in association with melanomas in seven families. They applied the initials of the first family, which were B.K., to name this clinical entity the B-K mole syndrome.

Differential diagnosis

The clinician is faced with the task of differentiating the malignant melanoma from a number of other lesions that may clinically resemble melanoma, such as seborrheic keratosis (Fig. 29.7A), pyogenic granuloma (Fig. 29.7B), and pigmented basal cell carcinoma (Fig. 29.7C). This differentiation may sometimes be difficult because of recent growth, bleeding into a lesion, or peripheral inflammation. In these instances, only microscopic examination of the tissue provides the proper diagnosis.

Extensive or radical surgical procedures should not be performed without the proper diagnosis of a melanoma because clinical impressions are not uniformly correct. Epstein *et al.*²⁸ reviewed 559 patients with black lesions that they believed might be melanomas. They found that their diagnosis of melanoma was correct only a third (38.7%) of the time. The most common diagnoses were benign nevi (35%), pigmented basal cell cancer (30%), and benign angiomas or vascular lesions (13%). Only 2% of the lesions were found to be melanoma. Dermoscopy, the use of a hand-held lens in combination with oil immersion, has been shown to improve diagnostic accuracy in skilled hands.^{29,30} However, it is used routinely by only 23% of dermatologists.³¹ In general, the diagnostic work-up of melanocytic lesions will precede the surgeon's involvement, unless the lesion is in a region of cosmetic concern.

Hutchinson freckle

A Hutchinson freckle is a flat, brown, macular lesion that may grow at various rates and achieve different shades of pigmentation (Fig. 29.8). This lesion occurs most commonly on the face, neck, and other sun-exposed surfaces of adults in middle age or later. On histologic examination, this lesion appears as an overgrowth of melanocytes at the epidermis–dermis junction. Although lentigo maligna is an *in situ* melanoma, invasive melanoma may develop within a Hutchinson freckle and is then called lentigo maligna melanoma.

Melanoma

Melanoma lesions may be flat or nodular, with significant darkening, erythema, or bleeding. On histologic examination, the earliest lesions demonstrate atypical melanocytes migrating above the dermis–epidermis junction and appearing

Fig. 29.7 Pigmented lesions that need to be differentiated from a melanoma. (A) Seborrheic keratosis of cheek is a velvety smooth keratosis that may turn dark brown to black with drying of the keratin layer. (B) Pyogenic granuloma with exophytic granulation tissue and darkening due to desiccation of the blood and coagulum. (C) Pigmented basal cell carcinoma with heaped up “pearly” margins. Pigment may represent hemosiderin or melanin granules from melanocytes that may be incorporated into the lesion.

within the upper portions of hair follicles and eccrine ducts. These changes are typical of melanoma *in situ*.³² Special staining with S100 and HMB45 may be necessary to confirm the diagnosis in cases with histologic features that may be equivocal. However, when even a single atypical melanocyte invades from the dermis–epidermis junction down into the dermis, the diagnosis is melanoma.³³

There are clinical features of pigmented lesions that are characteristic for melanoma. These criteria have been promoted by the American Cancer Society as the ABCD Guidelines (Fig. 29.9).

- A Asymmetry of the lesion as it grows from a round or oval lesion
- B Border irregularity, which is a result of irregular growth rates of different parts of the lesion
- C Color changes representing pigment granules deposited at varying depths in the dermis, depending on the rate of invasion
- D Diameter of the lesion becoming more than $\frac{1}{4}$ inch (>6 mm)

In addition to the above ABCD criteria, a review of the literature recommended the addition of E for “evolution”, in order to emphasize the significance of evolving pigmented lesions in the natural history of melanoma, especially given the existence of small-diameter (≤ 6 mm) melanomas.³⁴ In treating patients with suspicious pigmented lesions, physicians should be attentive to changes (evolving) of size, shape, symptoms (itching, tenderness), surface (especially bleeding), and shades of color. An investigation of the recognition process of melanoma by 135 dermatologists revealed that most dermatologists rely more on the lesion’s overall pattern, the “ugly duckling sign” (i.e., unique appearance relative to the patient’s other nevi), and recent change according to the patient, rather than the more well-known ABCD algorithm.³⁵ This observation lends support to the addition of an E category for evaluation of melanocytic lesions by the non-dermatologist.

Based on existing literature, most patients who present to their dermatologist are unaware of an existing melanoma. Most melanomas (56.3%) detected in the general dermatology practice are found by the dermatologist during routine physical examination, and are not part of the presenting

Fig. 29.8 Hutchinson freckle is a flat lesion with various shades of pigmentation.

complaint.³⁶ Numerous studies^{37–39} demonstrate that physicians are more likely to detect melanomas at a thinner stage than non-physicians. In these studies, there was a significant difference between the thickness of physician-detected melanomas (0.23–0.68 mm) and those detected by patients or their spouses (0.9–1.43 mm).

An occasional, and potentially reassuring, feature of melanoma is intralesional depigmentation (Fig. 29.10). This is a manifestation of immunologic regression of the tumor as a result of the destruction of the melanoma cells by the host's immune system. The histologic examination of only a section through the depigmented portion may be misread as an inflammatory reaction. However, deposits of residual melanin granules may exist in the depigmented portion (Fig. 29.10B), and histologic examination of sections through the adjacent pigmented portion may reveal the true diagnosis of the melanoma.

Nevertheless, depigmentation does not always indicate melanoma; a halo nevus (Fig. 29.11A) is a benign lesion with a peripheral ring of depigmentation.⁴⁰ Histologic examination of the halo portion shows lymphocytic infiltration without pigment granules (Fig. 29.11B). Further evaluation of the lesion and surrounding tissue shows no evidence of cells of malignant melanoma (Fig. 29.11C).

Multiple primary melanomas

Multiple primary melanomas have been reported to occur among 3% of melanoma patients.⁴¹ The risk for a second melanoma in a patient with one melanoma approaches 4% to 5%.⁴² However, with a positive family history of melanoma, the risk for multiple primary melanomas rises to 10% or more.⁴³ The highest risk of all appears to be in individuals who have a family history of melanoma in one or two first-degree relatives and who have clinical evidence of dysplastic nevi, suggesting

a probability approaching 100% in time.⁴⁴ Although multiple primary melanomas may be found among 10% of the patients, Ariyan *et al.*⁴⁵ reported that half of these subsequent melanomas are *in situ*, and the vast majority of the rest are less than 1.0 mm thick; thus, they did not seem to affect cure rates.

Classification/staging of disease

Melanoma is most commonly located in the skin, although it may also occur rarely in the mucosa of the oral cavity, nasopharynx, esophagus, vagina, and rectum. The staging system developed for melanoma applies to lesions arising in the skin, and thus, the discussion in this chapter is primarily limited to cutaneous melanoma.

The purpose of a classification system in malignant disease is to separate varying stages of severity to predict prognosis and to propose treatment options based on those predictions. Therefore, all classification systems have evolved from data collected over time. As such, each of these classifications needs to be re-evaluated periodically to refine the separation of stages on the basis of changes in outcome. Melanoma staging has evolved to include important data acquired from pathologic analysis of the initial biopsy (and potential biopsy of regional lymph nodes).

The most recent (2017), eighth edition of the American Joint Committee on Cancer (AJCC) staging system relies upon data related to the primary *tumor* (T), regional *lymph nodes* (N), and *metastases* (M). Also known as the TNM system, this staging system was developed based upon analysis of over 38 900 patients with cutaneous malignant melanoma⁴⁶ (Tables 29.2 & 29.3).

Histologic subtypes of melanoma

While morphology, or histologic subtype, does not necessarily correlate with clinical behavior, subclassification is important for pathologic recognition and diagnosis. Melanoma may be classified morphologically into four major growth patterns: lentigo maligna, superficial spreading, nodular, and acral lentiginous types (Fig. 29.12). Superficial spreading melanoma (Fig. 29.12B) represents 50% to 80% of all the types and is characterized by growth in the radial (horizontal) phase for a period of years before evolution into the vertical growth phase. Nodular melanoma (Fig. 29.12C), on the other hand, evolves into the vertical growth phase early in its development and represents 20% to 30% of the group but in some series may compose the majority of the lesions.⁴⁸ Lentigo maligna melanoma (Fig. 29.12A) is differentiated from superficial spreading melanoma and nodular melanoma by its location on sun-exposed surfaces of the body and within pre-existing lentigo maligna (Hutchinson freckle). This morphologic type of melanoma was believed to have a better prognosis than other types by virtue of a different biologic behavior, but it has been shown to have a prognosis identical with that for superficial spreading melanoma with comparable depths of invasion.⁴⁹ It has been shown that lentigo maligna melanoma merely grows in a horizontal fashion more than in a vertical fashion, resulting in thinner lesions than superficial spreading melanoma or nodular melanoma, which is the reason for its purported better prognosis.

Acral lentiginous melanoma appears on the palms of the hands, soles of the feet (Fig. 29.12D), subungual areas of the

Fig. 29.9 Melanoma with characteristic changes. (A) Asymmetry of lesion shape. (B) Border irregularity. (C) Color variegation. (D) Diameter greater than 6 mm.

Fig. 29.10 (A) Melanoma with areas of depigmentation within the lesion. (B) Histologic examination of the specimen cut through the area of depigmentation shows significant lymphocytic infiltration with disrupted pigment granules leading to the colorless patches within.

Fig. 29.11 (A) Halo nevus with a ring of depigmentation surrounding the lesion. (B) Histologic examination of the depigmented portion shows infiltration with lymphocytes, but there is no evidence of pigment granules or malignant cells (C).

fingers and toes (Fig. 29.12E), and web spaces.⁵⁰ The importance of subungual melanoma is that it is often erroneously believed to be a fungal infection, and appropriate treatment may be inadvertently delayed because of a delay in obtaining diagnostic biopsy. Presumably due to delayed diagnosis, this type of melanoma has the lowest 5-year survival rates of all histologic variants, generally found to be in the range of 10% to 20%.^{25,51}

While older studies suggested that prognosis may be associated with histologic subtype (e.g., patients with nodular melanomas were thought to have a worse prognosis than patients with superficial spreading melanomas),⁵² more recent multivariate analyses demonstrate that these prognostic differences are more likely due to other histologic features (i.e., tumor thickness and ulceration).⁵³

Another less common clinical variant of melanoma, desmoplastic melanoma, usually does not produce pigment, and grows on the external surfaces of the skin. It may have the appearance of a hypertrophic scar (Fig. 29.13A) at a location where the patient does not recall having had an injury to the skin. It must be differentiated clinically from a dermatofibroma and other benign or malignant tumors of the dermis. Histologic examination reveals a cicatricial growth of the lesion with spindle cell variants of malignant melanocytes (Fig. 29.13B,C).^{54–56} This histologic subtype must be differentiated from amelanotic melanoma (Fig. 29.14), which is simply a variant of nodular or superficial spreading melanoma that is not producing sufficient pigment granules to appear as a pigmented lesion. In one series of melanomas, the incidence

of amelanotic melanoma was found to be 1.8%.⁵⁷ Desmoplastic melanoma (DM) is subtyped to those that are pure DM (100% are spindle cells) and those that are mixed DM (not all are spindle cells), because of the lower risk of nodal metastases reported in the pure DM.⁵⁸

Histopathologic factors of prognostic significance

With respect to analysis of the primary lesion alone, the depth of invasion of melanoma into the dermis has been shown to be the most powerful determinant of outcome. In 1965, Mehnert and Heard⁵⁹ reported the earliest correlation of depth with prognosis. A few years later, Clark *et al.*⁶⁰ described the following system of levels for the classification of depth of invasion into the dermis (Fig. 29.15):

Level I: *In situ* melanoma; limited to the dermis–epidermis junction

Level II: Invading the papillary dermis but without expansion of this layer

Level III: Invading and expanding into the papillary dermis but not into the reticular dermis (to the interface of the papillary–reticular dermis)

Level IV: Invading the reticular dermis, but not into the subcutaneous fat

Level V: Invading the subcutaneous fat or the associated subreticular tissues

Table 29.2 Cutaneous melanoma TNM staging (AJCC 8th Edition)

T classification	Thickness	Ulceration status
Tis	not applicable	not applicable
T1	≤1.0 mm	a: <0.8 mm w/o ulceration b: <0.8 mm with ulceration 0.8–1.0 mm with or w/o ulceration
T2	1.01–2.0 mm	a: w/o ulceration b: with ulceration
T3	2.01–4.0 mm	a: w/o ulceration b: with ulceration
T4	>4.0 mm	a: w/o ulceration b: with ulceration
N classification	No. of metastatic nodes	Nodal metastatic mass
N1	1 node	a: clinically occult micrometastasis* b: clinically detected macrometastasis** c: in transit met(s)/satellite(s) <i>without</i> metastatic nodes
N2	2–3 nodes	a: clinically occult micrometastasis* b: clinically detected macrometastasis** c: in-transit met(s)/satellite(s) <i>with</i> 1 metastatic node
N3	4 or more metastatic nodes, or matted nodes, or in-transit met(s)/satellite(s) <i>with</i> metastatic node(s)	a: clinically occult micrometastases* b: 1 clinically detected micrometastasis** c: 2 or more clinically detected micrometastases
M classification	Site	Serum LDH
M1a	Distant skin, subcutaneous or nodal metastases	(0): normal (1): elevated
M1b	Lung metastases	(0): normal (1): elevated
M1c	Other visceral (non CNS) metastases	(0): normal (1): elevated
M1d	Distant CNS metastasis	(0): normal (1): elevated

*Micrometastases are clinically occult nodes diagnosed after sentinel node biopsy.
 **Macrometastases are defined as clinically detectable nodal metastases confirmed by therapeutic lymphadenectomy or when nodal metastasis exhibits gross extracapsular extension.

(Source: Gershenwald JE, Scolyer RA, Hess KR, et al. Melanoma of the Skin. AJCC Cancer Staging Manual. 8th Edition. Springer; 2017, pp. 563–585.)

The difficulty with this classification system is the qualitative and somewhat subjective nature of determining the depth of invasion. Various pathologists examining a histologic slide of mid-dermal invasion often disagree on the Clark level of invasion; some may call it a level III, while others call it a deep level II, and still others call it an early level IV invasion. As a result of this difficulty, Breslow⁶¹ reported a method of quantitative measurement that employs a simple and readily reproducible system of microstaging. According to Breslow, the melanoma's depth of invasion is measured in tenths of millimeters as a thickness from the surface of the tumor in the epidermis to the deepest tumor cell identified by means of an ocular micrometer on the microscope. In a number of studies using multivariate analyses,^{46,48} Breslow's method has been shown to be the most powerful prognostic indicator for survival in early stage melanoma (i.e., disease limited to primary tumor). Additional factors shown, in appropriate multivariate analyses of several thousand patients, to be associated with recurrence and survival include: ulceration in the lesion, the mitotic rate within the lesion, the patient's age and sex, the site of the primary lesion, and the morphologic type of melanoma.^{46,62}

T category of TNM staging system

The histopathologic factors incorporated into the T category of the 2017 TNM staging system are the thickness of the primary tumor, i.e., the Breslow depth,⁶¹ and the presence or absence of ulceration of the overlying epithelium.⁴⁶

The thickness of the primary tumor (T) defines four categories (see Table 29.2):

T1: ≤1.0 mm

T2: 1.01–2.0 mm

T3: 2.01–4.0 mm

T4: >4.0 mm

Fig. 29.12 Various morphologic types of melanoma. (A) Lentigo maligna melanoma – thin, flat lesion within patchy discoloration of Hutchinson freckle. (B) Superficial spreading melanoma – flat lesion with cells proliferating in the horizontal plane. (C) Nodular melanoma – thicker lesion growing in a vertical plane. (D,E) Acral lentiginous melanoma of the foot and nail bed.

Increasing tumor thickness is closely correlated with poorer prognosis. The 10-year survival decreases progressively, from 96% for patients with primary lesions <0.5 mm thick to 54% for patients with lesions 4.01 to 6.0 mm thick.⁴⁶

The T categories are further subdivided into “a” or “b” based upon the presence or absence of ulceration (see [Table 29.2](#)). Ulceration is defined as the absence of an intact

epithelium over the melanoma. Outcomes in patients with ulcerated primary tumors are worse than in patients with primary melanomas of the same thickness but without ulceration. The mitotic rate was incorporated into the previous 2010 TNM staging system based upon the observation that it was the second most important prognostic factor in over 11000 patients with localized melanoma analyzed in the

Fig. 29.13 (A) Desmoplastic melanoma is often nonpigmented and has the appearance of hypertrophic scar. (B) Low-power magnification of the desmoplastic melanoma shows the proliferation of the tumor in a cicatricial fashion. (C) High-power magnification of the lesion shows the spindle cell variant of the malignant melanocytes with the production of some pigment granules.

AJCC Melanoma Staging Database. In that series, there was a highly significant correlation between increasing mitotic rate and declining survival rates ($p < 0.0001$). For instance, for melanomas less than 1.0 mm thick, the 10-year survival rate was 93% for those with <1 mitosis/mm² and 48% for those with >20 mitoses/mm².^{46,47} The previously recommended approach to determining the mitotic rate was to identify the area of dermis containing the most mitoses (the “hot spot”), and average the number of mitoses within a 1-mm² area of the hot spot.⁴⁷ The substaging according to mitotic rates applied only to T1 lesions.

With respect to prognostic classification (see Table 29.3), Stage I melanoma defines patients with low-risk melanomas (T1a–T2a) without evidence of regional or distant metastases. Further subdivision (Stages IA and IB) is based upon characteristics of the primary tumor. Stage II melanoma includes primary tumors at a higher risk of recurrence or metastasis (T2b–T4b) without evidence of surgical or distant metastases. Similarly, stage II subdivision (IIA, IIB, IIC) is based upon characteristics of the primary tumor.⁴⁶ Details of more advanced stages of melanoma will be covered in the next section.

In-transit and regional lymph node disease

Local metastatic spread of cutaneous melanoma is known to occur through lymphatic channels in the majority – approximately 90% – of cases.⁶³ Direct hematogenous dissemination of melanoma, more difficult to assess and treat, is another less common route of metastasis. There are a number of clinical and pathologic characteristics of regional spread of metastatic melanoma that have become incorporated into the prognostic staging system for primary melanoma, namely satellite/in-transit metastases and sentinel lymph node status.⁶⁴

Intralymphatic spread of melanoma in the skin can present/manifest as satellite lesions, also known as *microscopic satellitosis*, or *in-transit metastases*, which are skin or subcutaneous metastases more than 2 cm from the primary lesion.⁵³ Microscopic satellitosis is seen in up to one-third of primary melanoma lesions greater than 3 mm thick, compared to less than

Fig. 29.14 The lack of pigment production in this amelanotic melanoma is deceptive in a lesion that is otherwise suggestive of malignancy.

Fig. 29.15 The Clark classification of melanoma is dependent on the qualitative determination of the extent of invasion into the various areas of the dermis or subcutaneous fat. The Breslow classification is determined by the micrometer reading of the depth of invasion into the dermis, measured in tenths of millimeters.

5% of thinner lesions.⁶⁴ The presence of microscopic satellitosis and in-transit metastases has been shown to carry a poorer prognosis, similar to the presence of regional lymph node metastases.⁴⁶ Thus, in the current AJCC system, patients with microscopic satellitosis or in-transit metastases are upstaged to the level of a patient with established lymph node metastases (see [Tables 29.2](#) and [29.3](#)).

Spread of melanoma to the regional lymph nodes portends a poorer prognosis. As melanoma is known to mostly metastasize through lymphatic channels (and the first sites of metastasis are typically regional lymph node basins), evaluation of the regional lymph node basins has become critical in the staging of melanoma. Unfortunately, clinical evaluation of the regional lymph nodes is often inaccurate; as many as 20% of clinically node-negative patients have metastatic involvement on pathologic evaluation, and up to 20% of those with clinically positive nodes are pathologically negative.⁶⁵

Mostly of historical significance, elective lymph node dissection (ELND) has largely been supplanted by SLNB. However, brief mention is warranted. In the setting of clinically node-negative disease, ELND involves removal of all lymph nodes in a suspected draining basin. The rationale is that removal of subclinical regional disease may provide a survival benefit over a therapeutic node resection performed after regional disease becomes clinically evident. Performance of this procedure is now controversial, in the era of lymphoscintigraphy and sentinel lymph node biopsy, especially as most melanomas are being diagnosed early (thinner and less invasive), and the morbidity associated with a completion lymphadenectomy can be quite significant. Additionally, while a few retrospective analyses suggested ELND might improve survival by 25–40 percent,⁶⁶ most prospective randomized trials have not demonstrated a survival benefit from ELND.⁶⁷

Lymphoscintigraphy (lymphatic mapping) and sentinel lymph node biopsy

In the skin, as in all parts of the body, arterial blood pressure diffuses serum and nutrient material out of the vessels into

the interstitial tissue to nourish the cells. The breakdown products of metabolism are then picked up by the veins and taken back into the systemic system. Because the pressure in the arteries is greater than in the veins, more of this vascular fluid is diffused into the tissue than is taken away by the vein. To avoid the consequences of edema, lymphatic vessels (the micro sump pumps of the system) draw away this excess fluid and take it to the regional lymph nodes to filter the product before returning it to the systemic vascular system. This filtering function of the lymph nodes allows detection and attack of foreign bacteria, antigens, and cancer cells. It was this principle that permitted Sappey⁶⁸ to show the lymphatic patterns of the human body in 1874 by injecting mercury into the skin. Sappey's lines are a helpful guide to determine the likely directions of lymphatic spread. Subsequent experience has shown that lesions located more than 2 cm above or below a "belt line" drawn through the umbilicus usually drain to the axillary or groin nodes, respectively. Lesions more than 2 cm on either side of the midline drain to the lymph nodes on that respective side. Lesions within 4 cm of the vertical and horizontal bands may go to any one of the pairs of options ([Fig. 29.16](#)).

As a result of potentially unclear lymphatic drainage patterns, Sherman and Ter-Pogossian⁶⁹ introduced lymphoscintigraphy in 1953. They injected radiocolloid gold (¹⁹⁸Au) intradermally and used a gamma counter to detect the concentrated colloidal isotope in the filtering lymph nodes. This technique has since been modified with various other isotopes and colloids of various particle sizes for specific diagnostic purposes. The intent of each of these modifications is to identify the lymphatic vascular pattern in the tissue being evaluated.

The technique of lymphatic mapping is helpful for predicting the pattern of spread for cutaneous melanoma metastases to regional draining lymph node basins, and it may be helpful in actually detecting metastases in melanoma of the extremities.⁷⁰ In particular, the test may be useful in patients with T2 or thicker lesions of the lower extremity for evaluation of the iliac and pelvic lymph nodes to determine the extent of

Fig. 29.16 (A,B) Lymphatic drainage as predicted by Sappey's lines. (Redrawn from Sugarbaker EV, McBride CM. *Melanoma of the trunk: the results of surgical excision and anatomic guidelines for predicting nodal metastasis*. *Surgery*. 1976;80:22.)

lymphadenectomy that may be indicated. The iliac nodes should certainly be removed if they appear to be involved, but a pelvic lymphadenectomy is not indicated if the para-aortic lymph nodes are involved because cure is unlikely in these cases.

The sites of lymphatic spread from melanoma at other locations, including the trunk and head and neck regions, may be also evaluated by radionuclide lymphoscintigraphy.⁷¹ Several radiocolloids have been employed for lymphoscintigraphy, including gold, sulfur, and antimony. Antimony sulfide colloid and technetium sulfur colloid have been found to be safe, and both give reliable information for determining appropriate lymph nodes for elective dissection among patients with truncal or head and neck melanomas (Fig. 29.17).

A lymphoscintigram can demonstrate predicted as well as unexpected patterns of lymph node drainage from lesions at primary sites. The test has been demonstrated as a reliable predictor of the sites of nodal involvement. In a prospective study of 51 consecutive patients with primary melanomas greater than 1 mm thick and observed for a mean of 45 months, 23% of the 35 patients who chose to undergo elective lymphadenectomy were found to have micrometastases to these lymph nodes; all were in the node groups detected by the lymphoscintigram.⁷² During the several years of their follow-up, 5 of the 16 patients (31%) who chose to be observed eventually developed clinical evidence of nodal metastases;

in each case, the nodes that were involved with tumor were at the very sites of drainage predicted by the lymphoscintigrams that were performed at the time of initial diagnosis (Table 29.4). During the 7-year interval of follow-up, no patient in either group developed metastases to any nodes not predicted by lymphoscintigraphy.

Sentinel lymph node biopsy

As stated previously, the availability of lymphatic mapping with SLNB has obviated a possible role for ELND in the treatment of cutaneous melanoma. The concept of the sentinel lymph node is based on the principle that all lymphatic fluid from specific tissues is filtered by lymph nodes, and as such the first (or sentinel) lymph node filtering a specific site can be removed and evaluated for metastasis of malignant cells. The validity of this entire principle is predicated on the tenets that: finite regions drain to a specific node; the sentinel node can be found; a negative biopsy finding means no other metastases exist; and a negative sentinel node is truly negative.

Morton⁶³ introduced the technique of detecting the sentinel lymph node with the intraoperative injection of vital blue dyes in the dermis surrounding the site of the primary melanoma. He identified the sentinel lymph node in more than 80% of the patients and reported that the false-negative

Fig. 29.17 Lymphoscintigram of a right scapular melanoma (A) demonstrates drainage to the right axillary lymph nodes (B), as well as the right lower cervical nodes (C).

Table 29.4 Reliability of lymphoscintigrams		
	ELND	Observe
Number of patients*	35 (70%)	16 (30%)
Lymph node metastases	8 (23%)	—
Subsequent lymph node metastases	—	5 (31%)
*51 patients with melanoma greater than 1 mm thick; 7-year follow-up (mean of 45 months). ELND, elective lymph node dissection. (Data from Stephens PJ, Ariyan S, Ocampo RJ, et al. The predictive value of lymphoscintigraphy for nodal metastases of cutaneous melanoma. <i>Conn Med.</i> 1999;63:387.)		

Table 29.5 Risk of detecting a positive sentinel lymph node	
Breslow depth	Risk of + SLN
<1.0 mm	4–7%
1.01–2.0 mm	12–20%
2.01–4.0 mm	28–33%
>4.0 mm	40–44%
(Data from Rousseau DL Jr, Ross MI, Johnson MM, et al. Revised American Joint Committee on Cancer staging criteria accurately predict sentinel lymph node positivity in clinically node-negative melanoma patients. <i>Ann Surg Oncol.</i> 2003;10:569–574 and Morton DL, Hoon DS, Cochran AJ, et al. Lymphatic mapping and sentinel lymphadenectomy for early-stage melanoma: therapeutic utility and implications of nodal microanatomy and molecular staging for improving the accuracy of detection of nodal micrometastases. <i>Ann Surg.</i> 2003;238:538–549.)	

rates had been about 5%. Subsequent investigators^{73–75} reported the use of preoperative lymphatic mapping and the intraoperative use of radiocolloids together with vital blue dyes with increased identification and successful removal of the sentinel lymph node to the range of 98% to 99% of patients with melanoma (Fig. 29.18). Based on studies of melanoma patients who underwent SLNB and subsequent completion lymphadenectomy of the respective lymph node basin, it can be assumed that if the sentinel lymph nodes are not involved, the entire basin should be free of tumor, in 96% of cases.^{63,73,76}

N category of TNM system

Sentinel lymph node biopsy has largely become the standard of care in the initial evaluation of cutaneous melanoma, particularly for patients with melanoma thicker than 1 mm in depth. The likelihood of finding nodal metastases in patients with tumors less than 1 mm in thickness is quite low (less than 10%).^{77–79} However, the presence of certain high-risk features, including ulceration and/or a high mitotic rate, may justify SLNB in thin melanomas.^{80–83} The likelihood of detecting metastatic deposits in an SLNB increases with the thickness of the primary lesion; for lesions <1.0 mm, 1.01 mm to 2.0 mm, 2.01 mm to 4.0 mm, and >4 mm, the risk is approximately 4–7%, 12–20%, 28–33%, and 40–44%, respectively (Table 29.5).^{84,85} The test is particularly useful for patients with intermediate thickness melanomas, 1–4 mm. However, it should still be considered in the treatment algorithm of patients with

Fig. 29.18 Sentinel node dissection. Blue dye injected into the dermis (A) at the site of the primary melanoma can be detected in the lymphatic vessels (B). The radiocolloid injected in the dermis is detected by the hand-held gamma counter (C) to localize the sentinel lymph node (D). A second node (E) was also identified adjacent to the first.

very thick tumors (greater than 4 mm) because even though this group of patients has a 65–70% risk of distant metastases, the SLNB may still provide important prognostic information, and obviate a subsequent lymphadenectomy in a number of patients who would subsequently develop enlarged nodes.⁸⁶

Based on analyses of the AJCC Melanoma Staging Database, nodal status has been demonstrated as the overriding factor predicting disease outcome.^{87–89} For patients with clinically detectable nodal disease (macrometastases), the characteristics of the primary tumor essentially become irrelevant with respect to predicting five-year survival. That is, thickness, ulceration, and mitotic rate do not maintain statistical significance on multivariate analysis.⁹⁰ As the majority of patients present without clinically apparent nodal involvement, the goal of SLNB is to identify patients with microscopic nodal metastases as early as possible so they might benefit

from the early removal of these metastatic nodes before the disease can spread any further, and to consider these patients for adjuvant therapy. In patients with nodal disease (including those with nodal disease limited to micrometastases), it has been demonstrated that the most important prognostic factor is the *number of involved nodes*.⁹⁰

The node (N) category of the 2017 edition of the AJCC Melanoma TNM system (see Table 29.2), includes the following designations:

Nx: Nodes are not assessable (e.g., previously resected for other reasons)

N0: No regional lymphatic metastases.

N1: One involved lymph node.

N1a: clinically occult micrometastasis;

N1b: clinically detected macrometastasis

N1c: in transit or satellite metastasis without metastatic nodes

N2: Two to three involved nodes

N2a: clinically occult micrometastases

N2b: at least one node with clinically detected macrometastasis

N2c: in-transit or satellite metastasis with one metastatic lymph node

N3: Four or more positive nodes, matted nodes, or in-transit/satellite metastases with one or more positive nodes

N3a: clinically occult micrometastases

N3b: one clinically detected micrometastasis

N3c: two or more clinically detected micrometastases

The presence of in-transit metastases, or nodal involvement, classifies the patient as Stage III, with subclassification (IIIA, IIIB, IIIC, or IIID) dependent upon the extent of lymphatic disease (see [Table 29.3](#)).

Evaluation of systemic disease

The evaluation of the patient with malignant melanoma requires a complete physical examination of the primary site and regional draining lymph nodes to detect any clinical evidence of satellite or in-transit lesions (metastases) in the skin or of metastases to lymph nodes. The abdomen needs to be examined for evidence of an enlarged liver, enlarged spleen, or abdominal masses that would suggest intra-abdominal metastases. The extent of examination and the tests ordered for such evaluations are predicated on the stage of the primary diagnosis ([Table 29.6](#)). A chest radiograph may be indicated to look for pulmonary metastases, and computed chest tomograms may add to the detection of small and early lesions. Liver enzyme function tests are simple, sensitive, and reliable for detecting liver metastases and, when results are negative, may serve as a baseline for later annual follow-up examinations. Serum lactate dehydrogenase (LDH) has been identified as an important, independent prognostic factor in patients with disseminated melanoma. The AJCC Melanoma Staging Database included 7972 patients with distant metastases, and one- and two-year survival rates were significantly lower in patients with elevated serum LDH (32% versus 65% and 18% versus 40%).⁴⁶ Therefore, serum LDH must be measured at the time stage IV disease is documented, as it provides important prognostic information.

Computerized scans

Although tomographic radiographs of the lungs are helpful in detecting pulmonary metastases, computed tomographic (CT) scanning of the chest and abdomen does not offer a significant advantage as an initial screening test over chest radiographs and liver function tests.⁹¹ Even though this imaging technique requires skillful interpretation for optimal use, analyses have shown that screening chest radiographs, a much less expensive modality, are just as useful as CT scans in detecting metastatic lesions at the time of the initial diagnosis. However, CT scans do offer the potential for superior detection of metastatic lesions in various organs, and they are quite useful for evaluating the brain ([Fig. 29.19](#)).

Table 29.6 Staging evaluation: tests recommended for determination of presence and extent of tumor spread

Primary tumor (no clinical evidence of other involvement)

Physical examination

Chest radiography

Liver function tests

Lymphoscintigraphy to detect sites of sentinel nodes (if primary tumor is 1 mm or more thick)

Local and regional disease (in-transit lesions or nodal involvement)

Physical examination

Liver function tests

CT scans

of chest and abdomen (to examine lungs and liver)

of pelvis if tumor involves lower extremities

of neck if tumor involves the head and neck

Lymphoscintigraphy to detect sites of sentinel nodes

Additional scans as indicated by clinical signs or symptoms

Distant organ metastases

Physical examination

Liver function tests and serum lactate dehydrogenase level

CT scans as indicated above

MRI scans if required to detect extent of soft tissue invasion

PET scans to detect extent of tumor involvement of vital organs (lung, liver, brain)

Fig. 29.19 CT scans of the brain can detect small lesions. In this patient, several lesions are identified in both hemispheres.

Whereas patients with primary melanomas thicker than 1 mm may be considered at moderate risk, those with lesions greater than 2 mm are considered at high risk for metastases. Patients with stage III disease are certainly candidates for intensive surveillance. These higher risk patients should be evaluated for distant organ metastases with chest and abdominal CT scans, which enable the physician to examine the lungs, the liver, and the spleen in one test. Enhanced brain CT scans should also be considered.

Fig. 29.20 Magnetic resonance imaging, in this case of the brain, demonstrates involvement of soft tissue by melanoma.

On the other hand, CT scans can be helpful for staging the disease in patients who present with local or regional extension of the disease. In some patients, the extent of the disease detected from the CT scans can be elaborated by the use of magnetic resonance imaging scans (Fig. 29.20). Positron emission tomography (PET) scan has been found to be valuable for evaluating patients for extension of their disease and assigning stage.^{92,93} The increased metabolism of the tumor is reflected in the increased uptake of radioactive-labeled glucose, which is represented by the brighter activity at the site of the metastases (Fig. 29.21). In the absence of infectious processes, the false-positive rate has been reported to be less than 5% with PET scans. The restrictions to the use of PET scans are the limited availability of the scanners and the greater expense for these studies.

M category of TNM system

The AJCC staging system categorizes patients with distant metastases according to the site(s) of disease involvement and the serum lactate dehydrogenase (LDH) level (see Table 29.2).⁴⁶ M1a, associated with the best prognosis, identifies patients with metastases limited to distant skin, subcutaneous or lymph node sites, and a normal (0), or elevated (1) serum

LDH. M1b denotes patients with lung metastases and a normal (0), or elevated (1) serum LDH. The patients with the worst prognosis are M1c, with metastases to other visceral (non CNS) sites, and M1d, with distant CNS metastasis (both also with a normal (0) or an elevated (1) serum LDH). With respect to staging (see Table 29.3), any M designation (i.e., the presence of any metastatic disease beyond the regional lymph nodes) places the patient in the Stage IV category.

While rare, patients will occasionally present with metastatic melanoma without an identifiable primary tumor. In these situations, if the patient has isolated metastases in the lymph nodes, skin, or subcutaneous tissues and an unknown primary, they are considered Stage III, as studies suggest they have a similar (or slightly better) survival rate compared to those with involved lymph nodes and a known primary tumor.⁹⁴⁻⁹⁸

Members of the AJCC Melanoma Task Force recently developed an electronic prediction tool for patients presenting with localized disease (<http://www.melanomaprognosis.net>). The prediction tool can be used to predict the 1, 2, 5 and 10-year survival rates from initial diagnosis (with a 95% confidence interval) for an individual patient based on his/her relevant clinical and pathologic information. The predictive models were developed and validated using a combined

Fig. 29.21 PET scan of the chest and abdomen (right) confirms the increased activity of metastatic lesions seen on CT scan in the lung (upper left) and liver (lower left).

database (n=28047) from 11 major institutions and study groups participating in the development of the AJCC Melanoma Staging System.⁹⁹

Surgical considerations and treatment

Initial biopsy

Some clinicians have questioned the safety in biopsy of malignant melanoma for fear that tumor cells might be disseminated through the blood stream. To evaluate this risk, Epstein *et al.*²⁸ reviewed 170 melanoma patients from the California Tumor Registry over a 4-year period, 115 of whom underwent biopsy of the melanoma before surgical treatment and 55 of whom had not. The 5- and 10-year cure rates, as well as relative cure rates by life-table analysis to eliminate differences in the age distribution of the two groups, were more favorable for those patients who had undergone a previous biopsy. The results of this study suggest not that biopsies improve the overall cure rates but that an incomplete removal of a melanoma by a surgical biopsy followed by the definitive surgery does not decrease the cure rate. Additional studies have confirmed this observation, one from the United States with 230 patients¹⁰⁰ and a subsequent study from Denmark¹⁰¹ with 225 patients followed up for a minimum of 5 years. The role of biopsy type in relation to survival was specifically analyzed by Lederman *et al.*¹⁰² in 472 patients; 119 underwent incisional biopsy (either punch or incision) and 353 had an excisional biopsy. After controlling for other factors, especially tumor thickness, no statistically significant difference was demonstrated between patients in the different biopsy type groups. Importantly, biopsy of the lesion (incisional or excisional) will make the diagnosis of melanoma as well as demonstrate the aggressiveness of the lesion by the degree of invasion into the dermis.

Our recommendation, if the lesion is small, is to perform an excisional biopsy with a 1–2-mm margin of normal-appearing skin to permit the pathologist to render a diagnosis reliably and to determine the thickest depth of invasion. However, if functional or cosmetic concerns prohibit easy removal of the entire lesion, an incisional biopsy or punch biopsy is an acceptable alternative. The only drawback of such a partial biopsy is that the final therapeutic excision may show a lesion that is classified with greater depth of invasion than had been initially discovered. In some cases, the patient would have been eligible for sentinel node biopsy if the proper depth had been assessed before wide excision and resurfacing. We do not prefer shave biopsy, though it may be acceptable when the index of suspicion is low and the lesion is broad (e.g., broad shave biopsy in some cases of lentigo maligna and melanoma *in situ* may increase diagnostic sampling), or in cases of suspected subungual melanoma.

As specific details from the biopsy specimen will dictate the next steps in management, the specimen must be assessed by a pathologist with expertise in the evaluation of pigmented lesions. Pathologic details that must be reported include: Breslow thickness in millimeters, histologic ulceration, mitotic rate per mm², peripheral and deep margin status, and Clark level (for lesions ≤1 mm in depth). Other histopathologic details of potential significance include: microscopic satellitosis, regression, tumor infiltrating lymphocytes, neurotropism, and histologic subtype.

Wide local excision

The purpose of wide local excision (WLE) of melanoma is to decrease the incidence of local recurrence, reported in the literature to range from 3% to 20%. In large series, the highest risk of local recurrence has been documented with primary tumors on the hands and feet, with a recurrence rate of 11% to 12%, whereas the risk is only 5% to 6% for tumors on the face, scalp, and ear.⁶²

It has generally been accepted that melanomas less than 0.76 mm thick are uniformly curable, as reported by Breslow.⁶¹ Breslow and Macht¹⁰³ reported in a small series of 62 patients with lesions less than 0.76 mm that neither local recurrences nor metastases developed, regardless of the width of resection margin. Day *et al.*¹⁰⁴ reported that although thin lesions have a good prognosis, the prognosis may be worse when the melanoma is located within the BANS area, an acronym for the upper *back*, upper posterior *arm*, posterior *neck*, and posterior *scalp*. On the other hand, Woods *et al.*¹⁰⁵ reported 11 deaths among 400 patients with melanomas less than 0.76 mm treated at the Mayo Clinic; seven of the melanomas were not within the BANS area at all. In a smaller series, Briggs *et al.*¹⁰⁶ reported that 10% of the patients with melanoma less than 0.76 mm died during their 10-year experience.

The World Health Organization (WHO)¹⁰⁷ evaluated the importance of the width of resection of the primary melanoma and the surrounding normal skin in a study of 593 patients with clinical stage I disease. Curability was not influenced by the resection margins but decreased with increasing thickness of the primary melanoma. In a large study of more than 3400 patients, Urist *et al.*⁶² noted that the recurrence rate of 146 melanomas of the neck was less than 2% even though most of the patients (84% to 87%) were treated with resection margins of only 1–2 cm.

In a study of 598 patients with clinical stage I melanoma, the New York University–Massachusetts General Hospital Melanoma Clinical Cooperative Group noted that resection margins of 1.5 cm or less were associated with a significantly greater incidence of recurrences than were resection margins greater than 1.5 cm. However, margins greater than 3 cm did not lead to a lesser recurrence rate.¹⁰⁸ Indeed, for melanomas greater than 2 mm thick, retrospective data suggest that margins less than 2 cm may decrease the cure rates.^{62,109–111}

The thickness of the melanoma is the key factor in determining the recommended margin of normal tissue to be excised. However, a recent systematic review and meta-analysis of randomized controlled trials of surgical excision margins in melanoma did not demonstrate a statistically significant difference in overall survival between narrow or wide excision margins.¹¹² Nonetheless, recommended margins have decreased progressively as a result of multiple large clinical trials that have examined the impact of margins on local recurrence (Table 29.7).

With respect to *in situ* melanoma, while there are no data from randomized trials to define the optimal extent of surgical resection, retrospective data support the use of 0.5-cm margins.^{19,113} For invasive melanoma, we recommend the following excision margins, based on data from multiple studies of optimal resection margins for malignant melanoma.^{114–123} For patients with Stage IA melanoma (≤1.0 mm in thickness), wide excision with a 1.0-cm margin is recommended. For lesions of 1.01–2.0 mm in thickness, a 1–2-cm margin is

(Sources: Sladden MJ, Balch C, Barzilai DA, et al. Surgical excision margins for primary cutaneous melanoma. *Cochrane Database Syst Rev.* 2009(4):CD004835 and Stone M. Initial surgical management of melanoma of the skin and unusual sites. In: Atkins MB, Weiser M, Tsao H (eds). *UpToDate*. 18.3 ed. Waltham, MA: UpToDate, Inc.; 2010.)

recommended, recognizing that a full 2.0-cm margin may be difficult to achieve in some areas of functional or cosmetic significance.¹²⁴ For lesions >2.0 mm in thickness, a margin of at least 2.0 cm is recommended.

In determining the extent of the operation, whether on the face or on the trunk, it is important to consider the impact of the scar on the patient's self-image. The Pigment Lesion Study Group of the University of Pennsylvania evaluated the extent to which patients were distressed by scars after melanoma resections.¹⁰⁸ The two factors that had a negative impact were the degree of surgical depression or indentation and the patients' preoperative perception of the scar to be expected. The actual scar length did not have as much of an effect as the

extent of depression of the scar. As such, skin grafts are acceptable for reconstructions of large resection sites, but they cause significant deformities (Fig. 29.22), which are usually avoided with flaps for coverage. The author has previously reported on the safety of coverage of these wounds with flaps.¹²⁵

Head and neck

Although the skin of the head and neck accounts for only 9% of total body surface area, 15–30% of all primary melanomas develop on the head and neck.^{126,127} High-risk melanomas of the face should be excised as outlined above and closed with

Fig. 29.22 Skin grafts provide adequate coverage for wide resections, but they can lead to significant deformities, as demonstrated in the infraorbital region (A) and scalp (B).

adjacent flaps. Although resurfacing the resection site with a skin graft is possible, the cosmetic results are not as acceptable as with a flap. A local or regional skin flap covers the wound with a far more satisfactory color match to the rest of the face than a distant flap (Fig. 29.23).

A difficult area to resurface is a surgical defect over the chin because this area requires skin that firmly adheres to the mandible, soft tissue for contour, and a good match of the skin flap to the remainder of the face. A distant flap simply does not provide a satisfactory color match. A wide excision of this area can be resurfaced satisfactorily with an advancement flap of the neck.

On occasion, the melanoma forms on the upper part of the cheek, requiring removal of skin from the lower eyelids. This

area cannot be resurfaced with a skin flap because it requires thin pliable covering. Resurfacing is best accomplished by employing a cheek advancement flap to cover most of the defect and a full-thickness skin graft to the eyelids. The best place to harvest this skin graft is from the ipsilateral or contralateral upper eyelid; the postauricular area may be an acceptable alternative.

In situations where tissue conservation is deemed necessary, frozen section analysis may be considered, but it does carry a risk of false negative report.¹²⁸ Additionally, while investigational, Mohs micrographic surgery may be considered in these situations, or when treating superficial lesions of large diameter (e.g., lentigo maligna). Large series report that Mohs surgery¹²⁹ may control the primary lesion, but

Fig. 29.23 Melanoma of the cheek (A) was treated with a wide excision of the primary site (B), a complete functional neck dissection (C), and coverage with a large cervicofacial myocutaneous flap incorporating the platysma muscle (D). One year postoperative photographs (E,F).

longer follow-up is required before widespread adoption of this technique.¹³⁰ Treatment of lentigo maligna with imiquimod has also emerged as an effective therapy.^{131–134} Recent published work has shown the effectiveness of treating residual *in situ* melanoma at the margins of surgical resections with imiquimod, confirmed with negative biopsies after adequate treatment.¹³⁵

Extremities

Thin melanomas of the fingertips may be excised and the defect reconstructed with volar advancement flaps (Fig. 29.24) to provide sensate coverage. Melanomas of the nail bed that are thin can be removed with the underlying periosteum (Fig. 29.25A,B); if the tumor has not penetrated through the periosteum, then the distal phalanx can be saved and covered with a full-thickness skin graft. Lesions of the finger thicker than 1 mm are more safely treated with an interphalangeal joint amputation (Fig. 29.26) or a ray amputation, depending on the extent of the tumor. Subungual melanoma of the fingers should be resected at the distal interphalangeal joint to preserve function.¹³⁶ Similarly, subungual melanomas involving the toes should be managed with digital amputation at the metatarsal-phalangeal joint.

Melanomas of the dorsum of the hand, the forearm, and the leg may be treated more readily with a wide excision. These surgical wounds have traditionally been covered with skin grafts with good success. However, coverage of these wide excisions with local flaps (Fig. 29.27) has been accomplished with successful control of the primary site and a more cosmetically acceptable result.¹²⁵ Furthermore, these patients do not need to have the arm or leg immobilized, and they have a shorter hospital stay than do those who have had skin grafts.

Melanomas of the toes and feet are usually of the acral lentiginous type. These tumors spread aggressively and have a high incidence of local and regional recurrences. Therefore, they are best treated by aggressive resections (Fig. 29.28). A significant advantage to the use of flaps in the lower extremity is that patients may be able to ambulate the day after surgery and leave the hospital much sooner than patients treated with skin grafts.

Trunk

Primary melanomas of the trunk may be excised with more liberal margins (as much as 2–4 cm if need be) and still be closed easily. Some areas may be closed by wide undermining and large advancement flaps. Otherwise, these areas may still be closed readily by one or more local flaps (Fig. 29.29). Deep fascia and muscle may be preserved if not involved by tumor invasion.

Lymphadenectomy

The decision to perform a lymphadenectomy in a patient with melanoma requires further thought. In patients who present with palpable lymphadenopathy, it is appropriate to confirm diagnosis with fine needle aspiration, core needle, or open biopsy of the clinically enlarged lymph node(s). In the absence of radiological evidence of distant metastases, wide excision of the primary site and complete dissection of the involved lymph node basin is indicated. For staging purposes, the number of positive nodes, the total number of nodes examined and the presence or absence of extranodal tumor extension must be recorded.¹²⁴ Of note, in the lower extremities, when PET or pelvic CT scans reveal iliac and/or obturator lymphadenopathy, or if a positive Cloquet's

Fig. 29.24 Melanoma of the fingertip (A) was excised with the nail, nail matrix, and nail bed (B). The wound was covered with a volar advancement flap (C,D). The thumb remained free of disease at 4 years postop (E).

lymph node is found, deep groin dissection should be considered.^{137,138}

The majority of patients, however, will present without clinical evidence of nodal disease, and some will require sentinel lymph node biopsy (for staging purposes). The decision regarding which patients should undergo SLNB is dependent upon the pathological stage of the primary lesion. As stated previously, SLNB should be considered for patients with primary melanomas that demonstrate aggressive biology. Specifically, this includes stage IA melanomas with adverse prognostic features (i.e., thickness ≥ 1.0 mm, positive deep margins, lymphovascular invasion, or young patient age), stage IB and II melanomas, as well as patients with resectable solitary in-transit stage III melanoma.¹²⁴ The decision regarding whether to proceed with SLNB is ultimately up to the patient and the treating physician, and should be performed at the time of WLE.¹²⁴

If the sentinel lymph node is negative, regional lymph node dissection is not indicated. If the SLN is positive, the patient should be offered complete dissection of the involved lymph node basin; 15–20% of these dissections will demonstrate melanoma in non-sentinel lymph nodes.^{139,140} It has been shown that factors related to the SLN can help predict the presence of melanoma in non-SLNs: size of the metastatic focus, number of metastatic foci, and extracapsular extension.^{141,142} Of note, these stage III patients should be considered for adjuvant treatment with interferon alfa, especially if they lack any serious comorbidity and have an otherwise reasonable life expectancy.

The Multicenter Selective Lymphadenectomy Trial (MSLT) was a large trial designed to address the role of lymphatic mapping with SLNB in determining prognosis and its impact on survival; the third of the five planned interim analyses was published in 2006.¹⁴³ The primary study group included 1347 patients with intermediate thickness melanomas (1.2 to 3.5 mm) who were randomly assigned to WLE with observation or WLE with lymphatic mapping and SLNB. In the observation group, if palpable nodal metastases became evident, the patient underwent completion lymphadenectomy. Likewise, in the SLNB group, if the SLNB was histologically positive, the patient underwent immediate completion lymphadenectomy. A survival benefit was not demonstrated for the overall study population randomly assigned to lymphatic mapping and SLNB. However, amongst the patients who had nodal disease, the patients in the observation group who subsequently developed nodal metastases had more involved nodes at the time of lymphadenectomy (3.3 vs. 1.4 nodes), and a significantly lower 5-year survival rate (52.4% vs. 72.3%). Nevertheless, the final report of the MSLT was published in 2014. There was no significant difference noted in the 10-year melanoma specific survival in the two groups in the study population where 20.8% were found to have nodal metastases and 79.2% had no metastases.¹⁴⁴

However, there is no place for the simple excision of the involved palpable lymph node alone because it is more than likely that additional lymph nodes have micrometastases.¹⁴⁵ This question will be answered by the MSLT-II trial in progress now. In the meantime, the only accepted treatment is a

Fig. 29.26 Thicker melanomas of fingers (A) need to be treated more aggressively with interphalangeal joint amputation (B) or ray amputation (C–E).

complete lymphadenectomy of the regional group of lymph nodes.

Cervical lymphadenectomy

Patients with melanoma of the face and anterior scalp (Fig. 29.30) who are selected for cervical lymphadenectomy because of positive sentinel lymph nodes should also be considered for superficial parotidectomy on the ipsilateral side because the preauricular lymph nodes are the first echelon of nodal drainage. A cervical lymphadenectomy (Fig. 29.31) can be performed with or without preservation of the spinal

accessory nerve, internal jugular vein, and sternocleidomastoid muscle to provide a more acceptable appearance and functional neck and shoulder muscles.¹⁴⁶

Axillary lymphadenectomy

The patient is placed in the supine position with the arm abducted and placed freely on two arm boards. The entire arm, including the hand, is prepared for surgery and draped, so that the arm can be moved as needed during the procedure. Make a prominent S-shaped incision with the midportion placed transversely across the apex of the axilla, with one limb

Fig. 29.27 Wide excisions of melanomas of the hands, forearms, and legs (A) may be treated with local transposition flaps (B) to allow the patient to use the extremities early in the postoperative period (C).

descending behind the anterior edge of the lateral border of the pectoralis major muscle (Fig. 29.32) and the second limb descending along the posterior border of the upper arm. Elevate the two opposing skin flaps at the level of Scarpa fascia to expose the axillary contents.

Identify the brachial vein along the arm and dissect proximally to the axilla, from the anterior portion of the upper arm toward the posterior portion. Dissect the entire axillary contents in this fashion, moving in a distal to proximal direction. Ligate and transect the branches of the brachial vein; leave the thoracodorsal artery, vein, and nerve intact, however.

Dissect the axillary contents from along the lateral border of the pectoralis major muscle, leaving the muscle fascia behind with the muscle. Free the contents from the posterior surface of the pectoralis major, which is then retracted to expose the pectoralis minor. Dissect the fat and lymphatic contents from behind both the pectoralis major and minor muscles and retract this material downward. Using a surgical sponge pad, sweep the axillary contents away from the chest wall in a caudad direction. This maneuver usually exposes the long thoracic nerve along the chest wall. Preserve this nerve.

After the axillary contents are removed, reposition the skin flaps and suture them closed over large suction catheters. These catheters remain in place for 3 to 10 days, depending on the amount of 24-hour drainage accumulated. The decision to remove the drain should be based on the pattern and rate of daily decrease in the drainage rather than the actual amount. The drains are most commonly ready to be removed by the fifth or sixth day. The patient is instructed to keep the arm in a sling during waking hours to decrease shearing forces on the dissected tissues and thereby lessen the drainage.

Pelvic and inguinofemoral lymphadenectomy

Excision of inguinofemoral lymph nodes is facilitated by a horizontal incision along the skin crease 2 cm above and parallel to the inguinal region and a vertical incision over the femoral vessels, beginning in the inguinal skinfold and extending inferiorly for 8 to 10 cm. This approach results in an “interrupted” T incision (Fig. 29.33). Carry the skin incision in the inguinal area down to the fascia of the external oblique muscle and split it open to expose the internal oblique muscle. Dissect this origin of the internal oblique muscle sharply off

Fig. 29.28 Melanoma of the plantar area (A) may be resurfaced with an arterial fasciocutaneous flap (B–E).

Fig. 29.29 In the truncal area, deep melanomas may be resected widely (A) and still be closed reliably with large transposition flaps (B).

the iliac crest to provide access to the retroperitoneal space. Pull the peritoneum away along the undersurface of the transversalis fascia from the external iliac vessels and lymph nodes. This provides an excellent view of the nodes for the pelvic lymphadenectomy.

Elevate the skin flaps on either side of the femoral incisions at the level of Scarpa fascia as well as the skin below the horizontal incision (Fig. 29.34). Elevate the skin completely from the inguinal incision to the lower end of the femoral incision. Dissect the femoral fat and lymphatic tissues down to but not including the muscle fascia. Continue the dissection cephalad

on the surface of the muscle fascia until the saphenous vein and saphenous bulb are reached on the femoral vein.

Dissect the contents in the inguinal region down to the fascia of the external oblique muscle and in the caudad direction to communicate with the femoral dissection. Do not remove the muscle fascia or transpose the muscles adjacent to the femoral vessels to cover these vessels; such procedures increase the risk of lymphedema. Close the wounds over large suction catheters that remain in place for 3 to 10 days. Patients are permitted to ambulate the night of surgery or the next morning.

Fig. 29.33, cont'd The fascia of the external oblique muscle is split (C), and the internal oblique and transversalis are dissected away from the inguinal ligament and iliac crest. The peritoneum is peeled back by finger dissection (D) to obtain retroperitoneal access to the iliac and obturator nodes (E).

Adjuvant treatment for melanoma

Wide local excision is the standard of care for early stage melanoma, and the majority of patients present with stage I–IIA disease. However, high-risk patients with stage IIB–III disease have a generally poorer prognosis. These patients have been the primary focus in development of adjuvant therapies for melanoma. Over the past 30 years, a number of efforts with chemotherapeutic agents (e.g., dacarbazine¹⁴⁷), nonspecific immune adjuvants (e.g., BCG vaccine¹⁴⁷), and hormonal agents (e.g. megestrol acetate), have not demonstrated a benefit over observation or placebo. The most promising results have been demonstrated with interferon alfa (IFN- α), an immune modulator that can induce antitumor activity.

Interferon alfa

Early clinical studies with IFN- α demonstrated modest anti-tumor activity in patients with metastatic melanoma. A series of clinical trials were then started to examine the role of adjuvant IFN- α in patients with high-risk melanoma. Each of these trials has different doses and schedules, and an optimal approach to the administration of IFN- α has not been established. Review of data combined from multiple randomized controlled trials demonstrates that IFN- α is associated with an improvement in relapse-free survival but not with overall survival.¹⁴⁸ The role for adjuvant IFN- α for patients with intermediate to high-risk melanoma remains undefined.¹⁴⁹ Treatment with adjuvant IFN- α should be made on an individual basis, after discussion with the patient, with discussion of the potential benefits and side effects associated with IFN- α .

Fig. 29.34 The femoral nodes are approached through a vertical incision over the region of the femoral vessels. After the medial and lateral flaps are elevated (left), the subcutaneous fat containing the lymph nodes is dissected off the deeper muscle fascia (right).

therapy.¹⁵⁰ For patients with stage IIB through stage III disease which has been resected, the National Comprehensive Cancer Network (NCCN) recommends consideration of adjuvant treatment with IFN- α or enrollment in a clinical trial.¹²⁴

Radiation therapy

When excision of a primary melanoma with appropriate margins is not possible, adjuvant radiation may be considered, though it is not generally recommended for the primary treatment of cutaneous melanoma. In some exceptional circumstances, for patients who are poor candidates for surgical resection, radiotherapy may offer an acceptable alternative for control of disease. Additionally, successful treatment of ocular melanoma with eye and vision preservation is one of the major triumphs of radiation oncology. Very high rates of local control can be achieved with particle radiation treatment or episcleral plaque brachytherapy.¹⁵¹

Early studies by Barranco *et al.*¹⁵² demonstrated that cultured malignant melanoma cells differ from other types of tumor cells in their radiosensitivity. They found that the relative radioresistance of melanoma could be overcome by increasing the individual dose fraction. These studies helped form the basis for clinical practice, and subsequent studies helped to determine the ideal fraction size and total therapeutic dose that effectively treats melanoma.

In patients with extensive facial lentigo maligna melanoma that precludes adequate surgical resection based on functional or cosmetic considerations, radiotherapy has been reported.¹⁵³ However, more recent advances in topical therapies such as imiquimod (Aldara®), are supplanting radiation therapy (RT) in the non-surgical treatment of lentigo maligna melanoma.

Early work by Habermalz and Fischer demonstrated some success with higher-dose radiotherapy over more frequent time intervals than conventional radiotherapy, with partial or complete regression especially seen with subcutaneous metastases.¹⁵⁴ Prospective nonrandomized clinical trials at M.D. Anderson Cancer Center, treating high risk groups of melanoma patients with radiation therapy, have helped establish the basis of treatment with hypofractionated radiation therapy in melanoma.¹⁵⁵ While locoregional control was improved with adjuvant radiation, distant metastases developed in a large number of patients (58 of 174 patients).¹⁵⁵ Later studies from this group evaluated the outcome of patients with clinically apparent cervical lymph node metastases from malignant melanoma managed with surgical resection and adjuvant radiation.¹⁵⁶ After 10-year follow-up, the group demonstrated a 94% regional control rate. Radiation-related complications for the patients were manageable.¹⁵⁶ The same group evaluated the utility of radiation therapy alone in the treatment of 36 patients with positive SLNB (in lieu of completion lymphadenectomy), and demonstrated 93% regional control over five years.¹⁵⁷ However, when recurrences present within radiated fields, the surgical management can be arduous and lead to breakdown and non-healing wounds.

Work from Australia and New Zealand, including the Trans Tasman Radiation Oncology Group, has provided the most meaningful data with respect to the role of adjuvant radiation therapy in the treatment of metastatic disease.¹⁵⁸ In a prospective study, 250 patients with positive lymph nodes deemed to be at high risk for locoregional recurrence were randomly assigned to radiation therapy (48 Gy in 20 fractions) or observation. Patients were considered high risk if there was extracapsular extension, multiple positive nodes

(≥ 1 parotid, ≥ 2 cervical or axillary, or ≥ 3 groin-positive nodes), and large lymph nodes (≥ 3 cm for parotid, neck, and axilla, and ≥ 4 cm for groin location). After a median follow-up of 40 months, the radiation arm showed a significantly lower rate of lymph node recurrence as compared with observation. However, there were no differences in relapse-free survival or overall survival.¹⁵⁹ An update presented at the American Society of Clinical Oncology 2013 meeting with 6-year median follow-up confirmed these findings. The 5-year local recurrence rate was 18% for the RT arm and 33% for the observation arm ($P < 0.02$), and no difference in relapse-free or overall survival.¹⁶⁰

The NCCN recommends consideration of adjuvant radiation therapy for patients with multiple positive lymph nodes, lymph nodes with extracapsular spread, nodal recurrence and in-transit metastases. Additionally, radiotherapy should be considered after excision of primary melanomas that demonstrate neurotropism (desmoplastic type),¹⁶¹ as well as mucosal melanomas, which may or may not be amenable to complete excision.^{162,163} Radiation therapy may also be used for palliative treatment of melanoma distant metastases. It is effective for pain, mass effect, tumor-related hemorrhage, and local irritation from skin and subcutaneous metastases.¹⁶⁴

Isolated limb infusion/perfusion

Tumor recurrences correlate with the thickness of the lesion. Between 60% and 70% of recurrences appear in the first 18 to 24 months after surgical treatments (Table 29.8; Fig. 29.35).¹⁶⁵ It is presumed that the earliest recurrences are to local or regional lymph nodes, followed by in-transit metastases; distant metastases appear last.

Patients with local recurrences may be treated with wider surgical resections, but extensive local recurrences or in-transit metastases are more difficult to treat. In-transit metastases of extremities may be treated with isolation-perfusion of that extremity with melphalan,¹⁶⁶ dacarbazine (DTIC),¹⁶⁷ cisplatin, or hypo-osmolar perfusions with carboplatin.¹⁶⁸ Carboplatin eradicated the lesions after perfusion in some patients (Fig. 29.36), whereas the control was temporary in other patients. The advantage of DTIC is its low incidence of hepatic and systemic toxicity, which is far less than that after perfusion with L-phenylalanine mustard. Indeed, we found that such

perfusions were tolerated well among our elderly patients, with no greater risk of complications in this group than in our younger patients (Table 29.9).¹⁶⁹ In general, the major role for isolated limb infusion/perfusion is palliation of unresectable limb disease.

Table 29.8 Timing of recurrent melanoma after surgical treatment

Site	18 months	24 months	3 years	5 years	10 years
Nodal	63%	74%	86%	93%	95%
Local	55%	67%	81%	88%	95%
In-transit	55%	67%	80%	90%	97%
Systemic	40%	52%	71%	83%	95%
Overall	57%	97%	81%	90%	95%

	14/47 (32%)				4/20 (20%)			

*67 perfusions in 60 patients, 1976–1995. (From Ariyan S, Poo WJ. The safety and efficacy of isolated perfusion of extremities for recurrent tumor in elderly patients. A 20-year experience. *Surgery.* 1998;123:335.)

Fig. 29.35 Patterns and timing of recurrences for melanoma. The curve of the timing of local recurrence and in-transit metastases precedes that of lymph node recurrences and distant organ metastases. (From Fusi S, Ariyan S, Sternlicht A. Data on first recurrence after treatment for malignant melanoma in a large patient population. *Plast Reconstr Surg.* 1993;91:94.)

Fig. 29.36 Regional isolated perfusion of a lower extremity recurrence (A) led to significant response and shrinking of the tumor (B is before perfusion, and C is after perfusion), permitting radical resection of the mass (D) without compromise to the popliteal vessels. At 1 year, there was no local recurrence (E).

Treatment of metastatic melanoma

It is well-established that the prognosis of patients with metastatic melanoma is poor; those with liver, brain, or bone metastasis have a median survival of only 6 months. Brain metastases occur in more than 50% of patients with advanced melanoma.¹⁷⁰ The median survival of these patients is 4.4

months and the 5-year survival rate is approximately 3%.¹⁷¹ A number of systemic therapy options are available to treat patients with metastatic disease, including single-agent or multiple-agent chemotherapy, biochemotherapy, radiotherapy, or strategies using immune modulation. However, little consensus exists regarding standard therapy for patients with metastatic melanoma. From the surgical perspective, if the patient has metastatic disease localized to a single small focus

Table 29.10 Surgery for metastatic melanoma: outcome

Site of first recurrence	Incidence	5-year survival	Median survival
Skin, fat, lymph node	50%–60%	5%–40%	8–50 months
Lung	15%–35%	5%–30%	8–20 months
Gastrointestinal tract Small bowel (35%–65%) Colon (10%–15%) Stomach (5%)	2%–4%	Minority of patients Mostly palliative for symptomatic relief	10–20 months
Brain (at autopsy, 50%–80%)	8%–15%	Unexpected (5%) 80%–90% have symptomatic relief	6–8 months
Liver (rarely single metastasis)	5%	Anecdotal cases	–

(Modified from Allen PJ, Coit DG. The surgical management of metastatic melanoma. *Ann Surg Oncol*. 2002;9:762.)

in the lung, liver, or brain, it may be worthwhile to consider resection (Table 29.10). However, multiple recurrences cannot be treated by surgery and require consideration of systemic chemotherapy and/or radiation therapy. More recent advances have shown a very high response rate to gamma knife treatment of single or few metastases to brain.

Chemotherapeutic agents

Dacarbazine (DTIC) remains a standard of care in community practice, and has been used as a standard for comparing the efficacy of new regimens.^{124,172} Combination chemotherapeutic regimens that include other cytotoxic drugs, such as bis(2-chloroethyl)nitrosourea (BCNU), cisplatin, lomustine, and hydroxyurea, have been reported. The trials comparing DTIC alone or in combination with other agents have shown a significant though brief improvement in survival.¹⁷³ Dacarbazine and temozolomide have been shown to have similar response rates (approximately 10–20%) and survival,¹⁷⁴ with median response duration averaging approximately 3–4 months.^{173,174} Temozolomide can cross the blood–brain barrier, making it an attractive agent for treating melanoma, which has a propensity for metastasis to the brain.

Combination chemotherapy regimens such as CVD (dacarbazine plus cisplatin and vinblastine) or the Dartmouth regimen (dacarbazine, carmustine, cisplatin and tamoxifen) initially reported higher response rates,^{175,176} but subsequent clinical trials have not replicated these high response rates.¹⁷⁷ Paclitaxel, alone or in combination with carboplatin, may provide clinical benefit to some patients with metastatic

melanoma, but the duration of clinical benefit is short (2–7 months).^{178,179}

Tumor vaccines

The development of melanoma-specific tumor vaccines has been predicated on several clinical observations and lines of basic investigation that indicate that the immune system can eradicate melanoma cells. Although a comprehensive review of available vaccine strategies is beyond the scope of this chapter, some of the more encouraging studies are reviewed.

Ganglioside GM2, an antigen overexpressed by many melanoma cells, given in combination with bacille Calmette–Guérin (BCG) or other immune adjuvants, was developed by Haughton *et al.* at Memorial Sloan Kettering Cancer Center. Initial clinical trials suggested promising results,¹⁸⁰ however, further studies failed to show clinical benefit with this adjuvant treatment. Kirkwood *et al.*¹⁸¹ reported their experience comparing high-dose interferon alfa-2b and GM2 ganglioside vaccine for patients with resected melanoma, demonstrating the advantage of interferon. Additionally, a randomized Phase III trial (EORTC 18961) of adjuvant GM2-KLH21 in 1314 patients with stage II melanoma was closed early by the data monitoring committee because of inferior survival in the vaccine arm.¹⁸²

A polyvalent melanoma cell vaccine, developed at the John Wayne Cancer Center, was shown to be capable of inducing humoral and cell-mediated immune responses to melanoma-specific antigens.^{183,184} Nevertheless, this vaccine was found not to be beneficial in a clinical trial. Dr. Steven Rosenberg and co-investigators at the surgery branch of the National Cancer Institute have identified other cancer vaccines by using specific peptide antigens recognized by autologous tumor-specific T-cell clone reactivity.¹⁸⁵ Peptide vaccines are most often administered with cytokine or cellular immune adjuvants such as dendritic cells. DiFronzo *et al.*¹⁸⁶ demonstrated that enhanced humoral responses in patients treated with polyvalent vaccines resulted in limited but improved disease-free survival. It is difficult to advocate any of the current vaccine strategies over another, and we recommend that patients with high-risk melanoma be enrolled into prospective trials to test these therapeutic strategies.

Adoptive T-cell transfer

Rosenberg developed the concept of adoptive T-cell transfer, whereby tumor-infiltrating lymphocytes (TIL) isolated from an excised tumor can be expanded in the laboratory and infused back into the patient. The goal is for these cells to attack the tumor cells with an increased strength than the body would otherwise provide. A phase II trial of adoptive T-cell transfer in patients with stage IV melanoma demonstrated an objective response in 50% of patients.¹⁸⁷

Interleukin-2

Interleukin-2 (IL-2) was approved by the Food and Drug Administration (FDA) for treatment of metastatic melanoma in 1998. High-dose intravenous bolus IL-2 treatment resulted in overall objective response rates of about 17%.¹⁸⁸ In a highly selected patient population (n=270), IL-2 was able to induce durable complete responses (median response duration over 59 months) in approximately 6% of patients and partial

responses in 10% of patients with metastatic melanoma, albeit with high levels of toxicity.^{189,190} One study demonstrated increased response rate in metastatic melanoma when IL-2 was given with the 210M peptide vaccine (22%) compared to IL-2 (13%) alone.¹⁹¹

Biochemotherapy

Given the individual success of chemotherapeutic agents and the biologically active agents (IFN- α and IL-2), biochemotherapy regimens were developed. By combining conventional chemotherapeutic drugs with biologically active agents, investigators were able to demonstrate modest improvement in response rates of metastatic melanoma. In single institutional phase II trials, biochemotherapy (cisplatin, vinblastine, dacarbazine, interferon alfa, and interleukin-2) produced an overall response rate of 27–64% and a complete response rate of 15–21% in patients with metastatic melanoma.^{192–194} A report of a small phase III randomized trial comparing sequential biochemotherapy (dacarbazine, cisplatin, vinblastine with interleukin-2 and interferon alfa administered on a distinct schedule) with combined cisplatin, vinblastine and dacarbazine (CVD) showed response rates of 48% for the biochemotherapy regimen compared to 25% for CVD alone; median survival for patients treated with biochemotherapy was 11.9 months vs. 9.2 months for CVD.¹⁹⁵ In a phase III randomized intergroup trial (E3695), biochemotherapy (cisplatin, vinblastine, dacarbazine, interleukin-2 and interferon alfa-2b) produced a slightly higher response rate and progression free survival than CVD alone, but it was not associated with either improved quality of response or overall survival in patients with metastatic melanoma.¹⁹⁶ Biochemotherapy was substantially more toxic than CVD. Additional attempts to decrease toxicity of biochemotherapy by administering subcutaneous outpatient IL-2 did not show a substantial benefit of biochemotherapy versus chemotherapy alone.^{197–199} A meta-analysis demonstrated that although biochemotherapy seemed to improve overall response rates, there was no survival benefit for patients with metastatic melanoma.²⁰⁰

Given the overall poor performance of these agents, continued basic and translational research is warranted. Pre-emptive strategies are also being developed. Because a majority of patients with cutaneous melanoma have some identifiable risk factor (i.e., sun exposure), chemoprevention using carotenoids and inhibitors of cyclooxygenase-2 (COX-2), vascular endothelial growth factor (VEGF) receptor, and cytochrome P-450 are actively being investigated.²⁰¹ Outcomes of this work are much anticipated.

Immunotherapy-immune modulators

Despite many preclinical and clinical studies evaluating multiple cytokines, vaccines, antibodies, and other types of immune modulation, alone or in combination with chemotherapy, only IL-2 for metastatic disease and *interferon alfa* for surgical adjuvant treatment have demonstrated sufficient success to warrant approval by regulatory authorities.^{148,189} Nevertheless, there has been continued optimism that immune modulation can become an effective treatment for patients with melanoma driven largely by key advances in tumor immunobiology, including the potential to manipulate and

disrupt immune activation checkpoints and tumor defense mechanisms; newer approaches to antigen presentation for immune activation; refinements to procedures for antigen-specific T-cell expansion; gene transfer to alter lymphocyte specificity and function; and the potential for discovery of improved predictive biomarkers to select patients for individual treatments.²⁰²

Along these lines, Hodi *et al.* induced autoimmunity in patients with metastatic melanoma using ipilimumab, an antibody directed against the cytotoxic T-lymphocyte-associated antigen CTLA-4.²⁰³ CTLA-4 is an immune checkpoint molecule that down-regulates T-cell activation, and blocking this molecule is known to promote antitumor immunity.²⁰³ In their multicenter clinical trial, patients with metastatic melanoma were randomly assigned to receive either an anti-CTLA-4 agent (ipilimumab), a vaccine based on a melanoma antigen, or a combination of the anti-CTLA-4 agent and the vaccine. An improvement in overall survival, as well as an improvement in progression-free survival and best overall response rate, was seen in the patients who received anti-CTLA-4 therapy, as compared with the patients who received the vaccine only.²⁰³

In addition to CTLA-4, another extensively studied interaction is between programmed death-1 receptor (PD-1) on the surface of activated T cells with its ligand (PD-L1) on antigen-presenting cells or tumor cells. PD-1, like CTLA-4, is expressed on the surface of activated T cells, and when it binds PD-L1, the immune response is attenuated. The expression of PD-L1 on tumor cells is thought to play a role in decreased immune response in the tumor microenvironment, contributing to tumor growth and spread.

Of note, the side-effect profile of ipilimumab deserves mention, as 60% of patients suffered adverse events, mostly immune related. However, this randomized, controlled trial showed that there was a significant improvement in overall survival among melanoma patients treated with ipilimumab. It will likely prove useful in patients with metastatic melanoma whose disease progressed while receiving one or more previous therapies.

Phase I studies of PD-1 and PD-L1 inhibitors have demonstrated promising results in patients with metastatic melanoma.^{204,205} Randomized controlled trials evaluating survival benefits for PD-1 and PD-L1 inhibitors are currently being performed. Like ipilimumab, anti-PD-1/L1 medications have mostly immune-related adverse events. Early studies have been reported that are examining the combination of anti-CTLA-4 and anti-PD-1 medications. Treatment with concurrent nivolumab (anti-PD-1 antibody) and ipilimumab results in higher adverse event rates than administration of the drugs separately; however, most adverse events were reversible. An impressive response rate of 40% was seen in patients receiving the concurrent dosing versus 20% in those treated with a sequenced regimen.²⁰⁶ A subsequent update on this trial demonstrated an 82% survival rate at 1 year for the concurrent regimen and a 75% survival rate at 2 years.²⁰⁷ These results show improved response rates with the combination of multiple immunotherapy agents, and suggest that patients who experience disease progression on one agent may still benefit from the alternate agent. Given the results of these studies, as well as additional trials, nivolumab was approved by the FDA in December 2014 for the treatment of advanced melanoma after the failure of other treatments.²⁰⁸

Molecularly-targeted treatment of metastatic melanoma

Molecularly-targeted chemotherapy for metastatic melanoma has changed dramatically since 2010, with the advent of small inhibitor therapies, especially for melanomas with BRAF mutations. It was demonstrated in 2002 that approximately 50% of human melanomas harbor an activating mutation in BRAF, an upstream component of the mitogen-activated protein (MAP) kinase pathway; the mutation is a substitution of glutamic acid for valine (the V600E mutation).²⁰⁹ Melanoma cells containing the BRAF mutation are dependent on MAP kinase signaling for their growth and survival.²¹⁰ These findings suggested the possibility that melanoma may be amenable to targeted therapy.

There are three FDA-approved MAP kinase inhibitors used for the treatment of malignant melanoma: 2 BRAF inhibitors (BRAFi), vemurafenib and dabrafenib, and the first-in-class MEK inhibitor (MEKi), trametinib. Their approval was based on randomized, phase III trials in which each of the investigational agents was compared against dacarbazine for patients with unresectable BRAFV600E(K)-mutant MM.^{211–213} Responses were seen early during treatment, most responses were partial, and the development of secondary resistance was seen in the majority of patients.²¹⁴

It seems clear that melanomas can be categorized by specific molecular changes that drive their proliferation;²¹⁵ targeting the activated pathways in individual tumors may lead to tumor regression and possible cure. This type of personalized cancer therapy will likely play a prominent role in the care of patients with melanoma and other cancers in the coming decade.

Surveillance

Patients treated at the Yale Melanoma Unit are initially monitored closely (Table 29.11), with increasing intervals each year. The importance of dermatologic evaluation, photo documentation, and close follow-up cannot be overstated. Education of the patient for early self-detection of recurrences together with interval physician follow-up has been most successful in maintaining an effective monitoring program.²¹⁶ Patients are examined for local or in-transit metastases at varying intervals based on the stage of the melanoma at diagnosis (Table 29.12).

Tumor recurrences correlate with the thickness of the lesion. Between 60% and 70% of recurrences appear in the first 18 to 24 months after surgical treatment (see Table 29.8).¹⁶⁵ The earliest recurrences are to local or regional lymph nodes, followed by in-transit metastases; distant metastases appear last. Screening is typically by physical examination, liver-function

Table 29.11 Surveillance guidelines

Office visits and physical examination	
Stage 0	Yearly by dermatologist or primary care physician
Stage I	Every 6 months for 5 years
Stage II–IV	Every 3 months for 2 years Every 6 months for 3 years
Metastatic surveillance	
Lactate dehydrogenase level and complete blood cell count	At each visit, at least yearly
Chest radiograph	Every other visit, at least yearly
CT scan ± PET	With laboratory test or chest radiograph abnormality, physical findings, or symptoms

serology, and chest X-ray, which will detect most recurrences. Routine screening with CT of the head, chest, and abdomen is not recommended, unless clinical suspicion for metastases is high. Chest X-rays and liver serology, despite a relatively low yield,²¹⁷ are inexpensive and useful for establishment of baseline values. The utility of PET or PET-CT imaging for the surveillance of affected patients is still under investigation. Additionally, the prospect of using specific serum screening tools such as tyrosinase mRNA detected by RT-PCR is both clinically exciting and ethically challenging.²¹⁸

The National Cancer Institute recommends that most patients without a family history and no atypical nevi should have follow-up evaluations every 6 months for the first 2 years. Thereafter, yearly follow-up is appropriate. Those with a family history or atypical nevi are followed up every 3 months.²¹⁶

Summary

Melanoma remains a challenging and important clinical problem, with a rapidly rising yearly incidence. Wide local excision remains the primary treatment modality for primary disease. Sentinel lymph node biopsy is indicated for patients with clinically negative nodes and primary lesions with aggressive features, generally, thickness greater than 1 mm. If the SLN is positive, completion lymphadenectomy is indicated for control of regional disease. Unfortunately, the overall cure rates for advanced melanoma have not significantly improved during the past several decades because we are unable to treat the subclinical micrometastases that are present

Table 29.12 Protocol for follow-up surveillance

	Physical examination	Chest radiography	Liver function tests	Imaging
Stage I, T1	Semiannual × 2 yr, then annually	–	–	
Stage I–II, T2–4	Every 3 months × 3 yr, then semiannually	Annual	Annual	
Stage III (lymph nodes positive)	Every 3 months × 3 yr, then semiannually	Annual	Annual	Annual or as indicated

in systemic organs at the time of the treatment of the primary melanoma. Once these metastases become evident clinically, there is little chance of cure by further surgery, chemotherapy, radiation therapy, or combinations of these treatment modalities. Adjuvant trials with chemotherapy and biochemotherapy have not demonstrated uniform success for any meaningful period of time. Therefore, we cannot overemphasize the importance of clinical trials, and patients with advanced melanoma should be encouraged to enroll in clinical trials testing different adjuvant strategies whenever possible. Recent successes in controlling metastatic lesions with molecularly-targeted treatments hold promise for personalized treatments for genetic mutations in the future.

46. Gershenwald JE, Scolyer RA, Hess KR, et al. Melanoma of the Skin. *AJCC Cancer Staging Manual*. 8th ed. Springer; 2017: 563–585. The most recent melanoma staging recommendations were made on the basis of a multivariate analysis of 30 946 patients with stages I–III melanoma and 7972 patients with stage IV melanoma. For patients with localized melanoma, tumor thickness, mitotic rate, and ulceration are the most dominant prognostic factors. For patients with regional metastases, components that define the N category are the number of metastatic nodes, tumor burden, and ulceration of the primary melanoma. All patients with microscopic nodal metastases, regardless of extent of tumor burden, are classified as stage III. For patients with distant metastases, the two dominant components defining the M category continue to be the site of distant metastases and serum lactate dehydrogenase level.
61. Breslow A. Thickness, cross-sectional areas and depth of invasion in the prognosis of cutaneous melanoma. *Ann Surg*. 1970;172:902–908. Alexander Breslow first described the use of an ocular micrometer to measure the maximal thickness of melanomas, and demonstrated a correlation of depth of invasion with patient outcome.
63. Morton DL, Wen DR, Wong JH, et al. Technical details of intraoperative lymphatic mapping for early stage melanoma. *Arch Surg*. 1992;127:392–399. Morton et al. first described the use of sentinel lymph node biopsy in the treatment of melanoma. This technique identifies, with a high degree of accuracy, patients with early-stage melanoma who have nodal metastases and are likely to benefit from radical lymphadenectomy.
85. Morton DL, Hoon DS, Cochran AJ, et al. Lymphatic mapping and sentinel lymphadenectomy for early-stage melanoma: therapeutic utility and implications of nodal microanatomy and molecular staging for improving the accuracy of detection of nodal micrometastases. *Ann Surg*. 2003;238:538–549, discussion 49–50.
112. Sladden MJ, Balch C, Barzilai DA, et al. Surgical excision margins for primary cutaneous melanoma. *Cochrane Database Syst Rev*. 2009;(4):CD004835. This systematic review summarizes the evidence regarding width of excision margins for primary cutaneous melanoma. Of the five randomized controlled trials, there was no statistically significant difference in overall survival between narrow (1–2 cm) or wide (3–5 cm) excision margins. Based on the individual trials and meta-analysis, current randomized trial evidence is insufficient to address optimal excision margins for primary cutaneous melanoma.
116. Veronesi U, Cascinelli N, Adamus J, et al. Thin stage I primary cutaneous malignant melanoma. Comparison of excision with margins of 1 or 3 cm. *N Engl J Med*. 1988;318:1159–1162.
123. Thomas JM, Newton-Bishop J, A'Hern R, et al. Excision margins in high-risk malignant melanoma. *N Engl J Med*. 2004;350:757–766.

152. Barranco SC, Romsdahl MM, Humphrey RM. The radiation response of human malignant melanoma cells grown in vitro. *Cancer Res*. 1971;31:830–833.
203. Hodi FS, O'Day SJ, McDermott DF, et al. Improved survival with ipilimumab in patients with metastatic melanoma. *N Engl J Med*. 2010;363:711–723. In this study, ipilimumab, which potentiates an antitumor T-cell response, demonstrated improvement in overall survival (10.0 months vs. 6.4 months) in patients with unresectable stage III or IV melanoma. Adverse events can be severe, long-lasting, or both, but most are reversible with appropriate treatment.
214. Flaherty KT, Puzanov I, Kim KB, et al. Inhibition of mutated, activated BRAF in metastatic melanoma. *N Engl J Med*. 2010;363:809–819. The authors conducted a multicenter, phase I, dose escalation trial of PLX4032, an orally available inhibitor of mutated BRAF, followed by an extension phase involving the maximum dose that could be administered without adverse effects. Patients received PLX4032 twice daily until they had disease progression. BRAF (v-raf murine sarcoma viral oncogene homolog B1) is a signal transduction molecule that has an activating mutation (glutamic acid for valine at amino acid 600; V600E) in half of all melanomas. In the dose escalation cohort, among the 16 patients with melanoma whose tumors carried the V600E BRAF mutation and who were receiving 240 mg or more of PLX4032 twice daily, 10 had a partial response and 1 had a complete response. Among the 32 patients in the extension cohort, 24 had a partial response and 2 had a complete response. The estimated median progression-free survival among all patients was more than 7 months. Treatment with PLX4032 in the majority of patients with tumors that carry the V600E BRAF mutation resulted in complete or partial tumor regression.

 112. Sladden MJ, Balch C, Barzilai DA, et al. Surgical excision margins for primary cutaneous melanoma. *Cochrane Database Syst Rev*. 2009;(4):CD004835. This systematic review summarizes the evidence regarding width of excision margins for primary cutaneous melanoma. Of the five randomized controlled trials, there was no statistically significant difference in overall survival between narrow (1-2 cm) or wide (3-5 cm) excision margins. Based on the individual trials and meta-analysis, current randomized trial evidence is insufficient to address optimal excision margins for primary cutaneous melanoma.

Inhibition of mutated, activated BRAF in metastatic melanoma. *N Engl J Med.* 2010;363:809–819. *The authors conducted a multicenter, phase I, dose escalation trial of PLX4032, an orally available inhibitor of mutated BRAF, followed by an extension phase involving the maximum dose that could be administered without adverse effects. Patients received PLX4032 twice daily until they had disease progression. BRAF (v-raf murine sarcoma viral oncogene homolog B1) is a signal transduction molecule that has an activating mutation (glutamic acid for valine at amino acid 600; V600E) in half of all melanomas. In the dose escalation cohort, among the 16 patients with melanoma whose tumors carried the V600E BRAF mutation and who were receiving 240 mg or more of PLX4032 twice daily, 10 had a partial response and 1 had a complete response. Among the 32 patients in the extension cohort, 24 had a partial response and 2 had a complete response. The estimated median progression-free survival among all patients was more than 7 months. Treatment with PLX4032 in the majority of patients with tumors that carry the V600E BRAF mutation resulted in complete or partial tumor regression.*

Implants and biomaterials

Timothy W. King and Charles E. Butler

SYNOPSIS

- What is a biomaterial? In order to discuss biomaterials, we must first define this term.
- There are many definitions of biomaterials but a widely used one from the National Institutes of Health defines a biomaterial as “any substance (other than a drug) or combination of substances synthetic or natural in origin, which can be used for any period of time, as a whole or part of a system which treats, augments, or replaces tissue, organ, or function of the body”.¹
- With the advent of tissue engineering and regenerative medicine in recent years, the definition has broadened to include “any material used in a medical device intended to interact with biological systems”, allowing for structures and combination devices that actively interact with the body to be included in the field.²
- Biomaterials can be synthetic (i.e., those made by humans) or biological (i.e., those produced by a biological system).
- Further classifications based on development stage or material characteristics are also common but are beyond the scope of this chapter.

Access the Historical Perspective section and [Box 30.1](#) online at

<http://www.expertconsult.com>

For the purpose of this chapter, biomaterials will be divided into the following general categories: metals, polymers, ceramics, glues, skin substitutes, and bioprosthetics.

Metals

In order to achieve the mechanical and biophysical properties desired for applications in medicine, combinations of metals, called alloys, have been developed. These alloys are designed to be inert and withstand the corrosive environment found

within the human body. In general, these alloys have mechanical properties that exceed the properties of the natural tissue they are supporting because, unlike natural tissues, they are unable to recover from deformation.

Stainless steel

Stainless steel has been used as a biological implant since the 1920s.⁶ Stainless steel was designed to prevent corrosion and consists of over 10 individual compounds which provide it with the desired chemical and mechanical properties. The stainless steels used in medical applications are iron-chromium-nickel alloys with at least 17% chromium ([Table 30.1](#)). The chromium creates a protective surface, which contributes to the alloy's anticorrosive properties. The most commonly used stainless steel alloy in medical applications is “316L” which, in addition to the chromium composition, has a low carbon content to prevent carbide formation, and a high nickel content to increase the strength and hardness of the alloy. Stainless steel has a relatively high tensile strength but is easily deformed (bent). While this is useful in some applications, such as the application of arch bars for maxillomandibular fixation, overall these mechanical properties are less desirable than other currently available materials such as cobalt-chromium and titanium. In addition, stainless steel can leach metallic ions into the surrounding tissues, causing a severe inflammatory reaction and pain, which may require surgical removal of the implants in some patients. Stainless steel is currently used in surgical wire and in arch bars. Historically rigid fixation systems utilized stainless steel but other alloys have replaced stainless steel in this application.

Cobalt-chromium

Historically, cobalt-chromium alloys have been one of the most significant biomaterials used in humans. Vitallium, a cobalt-chromium-molybdenum (Co-Cr-Mo) alloy (ASTM 75), was first described in 1932 to address some of the problems experienced with stainless steel. These alloys replace the iron

Historical perspective

The development of biomaterials has exploded over the past 50 years. In fact, prior to World War II, the term “biomaterials” did not exist. Although there have been reports of biomaterials being used, in the form of sutures, 32 000 years ago,^{2,3} the vast majority of biomaterials have been developed in the last 60 years. The modern era of medical implants might be attributed to a British ophthalmologist, Harold Ridley, in the late 1940s. He noticed that shards of canopy plastic that had been unintentionally implanted in the eyes of Spitfire fighter pilots who had been shot at by enemy machine guns seemed to heal without any adverse reaction. He concluded that the plastic used to make the Spitfire canopy, poly(methyl-methacrylate), might be used to make implant lenses for patients with cataracts. In 1949 he implanted the first artificial lens into a human. This observation and innovation were the precursors to the modern intraocular lenses that are now used over 10 million times per year for patients with cataracts.²

Around the same time, several independent groups of surgeons and engineers developed biomaterial-based implants such as vascular grafts, hip replacements, and heart valves. These innovators defined the foundations of biomaterial science in an era before principles for medical materials were established. By the 1950s, as surgeons, engineers, and scientists continued to create these new implant materials, it

BOX 30.1 Properties of an ideal implant

- Minimal foreign-body reaction
- Elastic or supple
- Can be tailored easily
- Good tissue incorporation
- Allows collagen ingrowth
- Promotes permanent tissue repair
- Good tensile strength
- Tolerates infected environment
- Minimal wound complications

(Modified from Cumberland VH. A preliminary report on the use of prefabricated nylon weave in the repair of ventral hernia. *Med J Aust.* 1952;1:143–144; and Scales JT. Materials for hernia repair. *Proc R Soc Med.* 1953;46:647–652.)

became clear that there were certain properties that an ideal implant would impart. Cumberland⁴ and Scales⁵ described the properties of an ideal implant (Box 30.1).

Remarkably, although these criteria were published about 60 years ago, they are still the fundamental properties that all modern biomaterials attempt to achieve.

with cobalt (~60% of the composition), increase the chromium to 25–30% for additional corrosion resistance, and contain 5–7% molybdenum for additional strength (see Table 30.1). Co-Cr-Mo alloy was used in some of the early craniofacial miniplates and screws and helped to revolutionize that field. The major disadvantage of Co-Cr-Mo alloys is the scatter artifact on computed tomography (CT) imaging. Because of this, and several other benefits, titanium has essentially replaced Co-Cr-Mo alloys in most biomedical applications.⁷ However, it is still used in dental applications.

Titanium

Titanium alloys were introduced into medical applications in the early 1980s.^{6,8} Since that time titanium has almost entirely replaced the other alloys in medical applications. This is because the titanium alloys are stronger, lighter, have higher resistance to corrosion, and generally cause less inflammation. Titanium also has less stress shielding (localized osteopenia secondary to the implant protecting the bone from normal loading) than other metal implants because they have less stiffness. Titanium alloys have less than 0.5% iron in them (see Table 30.1), which provides them with two additional beneficial properties: they do not set off metal detectors, and they do not create a significant artifact on CT or magnetic resonance imaging studies. Finally, titanium can form chemical bonds with the surrounding mineralized bone without the typical fibrous tissue forming between the implant and bone. This unique characteristic allows titanium to be used to create osteointegrated implants. In many cases pure titanium rather

than an alloy is used for medical implants. Plastic surgery applications of titanium include plates and screws for rigid fixation of bone and mesh for use in applications such as orbital wall reconstruction (Fig. 30.1).

Gold

Although gold is chemically inert, in its pure form it has poor mechanical properties. Thus, when some strength is needed (for example, in dental fillings), a gold alloy is used. For applications such as eyelid weights in patients with lagophthalmos,⁹ where strength is less of an issue, 24-carat gold alloy (99.9% w/w purity) is commonly used to insure chemical inertness.

Platinum

Like gold, platinum is an inert metal and is the material of choice for patients with gold sensitivity who are in need of an eyelid implant for lagophthalmos. Platinum is denser than gold, thus the eyelid implants have a lower profile and are less noticeable than gold implants.

Some formulations containing platinum have been shown to be immunogenic and thus have raised concerns over long-term exposure. Because the Centers for Disease Control state that short-term exposure to platinum salts may cause irritation of the eyes, nose, and throat and long-term exposure may cause both respiratory and skin allergies, the current Occupational Safety and Health Administration standard for soluble platinum salts is 2 mcg/m³ of air averaged over 8 hours.

Fig. 30.1 Titanium plates for midface reconstruction. **(A)** Various 2.0-mm plates and screws. The screws are 7, 5, and 3 mm in length (left to right). **(B)** Four-hole plates and screws for the 1.0-, 1.5-, 2.0-, and 2.3-mm plating systems. **(C)** A 1.0-, 1.5-, and 2.0-mm “L” plate. The screws are all 5 mm in length. Note that, by convention, the size of the plates is based upon the screw diameter.

Platinum is also used as a catalyst in the formation of some polymers. Platinum black, a fine powder (1 nm–1 μ m) form of platinum, is used in many of these reactions.¹⁰ Platinum black catalyzes the addition of hydrogen to unsaturated organic compounds and is used in the production of silicone gel breast implants (see below).

Platinum complexes have also been used as chemotherapy and show good activity against some tumors. Cisplatin, the best-known platinum chemotherapeutic agent, has activity against multiple types of cancer. However, it has some significant side effects, including cumulative irreversible kidney damage and deafness.^{11,12}

Polymers

Polymers are molecules composed of repeating subunits. They are typically defined as a backbone series of molecules with side chains that are covalently bound to the backbone molecules. The physical properties of the polymer are defined by the structure of the monomer, the number of monomer units in the polymer chain, and the degree of cross-linking (the amount of bonding between two polymer chains). As

polymer chains are cross-linked, the ability for them to move independently is decreased. For example, a polymer with freely flowing chains might exist as a liquid and, as the amount of cross-linking is increased, it can become a “gel” or “solid”.

Silicone

Silicone is probably the most maligned and misunderstood biomaterial used in medicine today. This is likely due to the controversy revolving around the use of silicone in breast implants. Silicone gel-filled breast implants were first introduced in the US in 1962 and consisted of two shells made of thick, smooth-walled silicone elastomer, filled with a viscous silicone gel material (dimethylsiloxane) and glued together. Multiple variations and modifications to the shell and gel were made over the years in an attempt to improve the outcomes of breast augmentation and reduce the associated complications. In 1988, the US Food and Drug Administration (FDA), out of concerns from reports of implant failure and allegations of resultant complications and illness, relabeled breast implants as class III medical devices, and called for data from manufacturers showing the safety and effectiveness of these devices.^{13,14}

In 1992, the FDA claimed that there was “inadequate information to demonstrate that breast implants were safe and effective” and placed a moratorium on silicone gel breast implants for cosmetic purposes but allowed their continued use for reconstruction after mastectomy, correction of congenital deformities, or replacement of ruptured silicone gel-filled implants due to medical or surgical reasons. In order to address this concern, the Department of Health and Human Services appointed the Institute of Medicine of the National Academy of Science (IOM) to begin one of the most extensive research studies in medical history. Their charge was to examine potential complications during or after silicone-based breast implant surgeries. In 1999, after reviewing years of evidence and research concerning silicone gel-filled breast implants, the IOM released a comprehensive report on both saline-filled and silicone gel-filled breast implants entitled *Safety of Silicone Breast Implants*.¹⁵ The IOM found that “evidence suggests diseases or conditions such as connective tissue diseases, cancer, neurological diseases or other systemic complaints or conditions are no more common in women with breast implants than in women without implants”. Most individual studies and all systematic review studies have also subsequently failed to find a link between silicone breast implants and disease.^{13,14}

In 2006, the ban imposed by the FDA was lifted and restrictions on the use of silicone gel-filled breast implants produced by the two manufacturers for breast reconstruction and for cosmetic breast augmentation ended. The FDA approval required a complete 10-year study on women who have already received the implants and a 10-year study on the safety of the devices in 40 000 women. It was also mandated that patients be given brochures explaining the risks.^{13,14}

So what is silicone? It is important to understand this question in light of the history of breast implants. Silicone is a family of polymers consisting of alternating silicon (Si) and oxygen (O) molecules. Table 30.2 shows the nomenclature of silicone. Siloxane, the basic repeating unit of silicone, consists of silicon, oxygen, and a saturated hydrocarbon (alkane) side group. Poly-dimethylsiloxane (PDMS) $[(CH_3)_2SiO]_n$ is the polymer used in most medical applications. PDMS is a very pure polymer that consists of the silicone backbone (silicon and oxygen) with two methyl side chains. It is one of the most inert biomaterials available for use in medical devices. Altering the length and molecular weight of the PDMS changes the mechanical properties and behavior of the silicone gel. PDMS molecules with less than 30 monomers are defined as low-molecular-weight formulations and have a viscosity similar to baby oil. High-molecular-weight formulations contain more than 3000 monomers and are solids. Controlling the degree of cross-linking, changing additives, and adjusting the curing process can also modify the mechanical properties of silicone. For example, the silicone gel found in breast implants is cured in a hydrosilation reaction where some of the methyl side chains (CH_3) are replaced by vinyl side chains ($CH=CH_2$) that then allow the silicone chains to cross-link with each other. This reaction is catalyzed by platinum and some residual platinum can be found in silicone gel breast implants. The silicone shell on breast implants is made of fully polymerized silicone with an amorphous (noncrystalline) silica filler added for strength (Fig. 30.2).

Other plastic surgery applications of silicone include facial implants for malar, nasal, and chin reconstruction or

Table 30.2 Silicone nomenclature

Term	Chemical formula	Description
Silicon	Si	Most abundant element on earth Does not occur naturally in its metallic state
Silica	SiO_2	Sand, marble, or quartz
Silicate	Na_2SiO_3	In one form, used as a desiccant (e.g., in anesthesia machines)
Siloxane	R_2SiO	Monomer of silicon and oxygen
Silicone	$[R_2SiO]_n$	Polymers of silicon and oxygen
Poly-dimethylsiloxane	$[(CH_3)_2SiO]_n$	The building block for most medical-grade silicone products, including breast implants

(Adapted from Miller MJ, Ogunleye OT. Biomaterials. In: Guyuron B, Eriksson E, Persing JA, et al., eds. *Plastic Surgery Indications and Practice*. New York: Saunders Elsevier; 2009:57–66.)

augmentation, and orbital floor reconstruction. Hand surgeons use silicone implants for arthroplasty, flexor tendon replacement, and bone block spacers. Silicone is beneficial in these applications because it is relatively inert, malleable, and deformable. Low-molecular-weight silicone was used in the past as an injectable soft-tissue filler. However, severe tissue reaction and migration of the silicone have led many physicians to avoid this application.

Silicone is probably the most studied implantable material available today. After over 35 well-conducted studies from many countries, there is no conclusive evidence that this material causes disease. Furthermore, medical-grade silicone is ubiquitous, being found in more than 1000 medical products as either a component or as a residuum from the manufacturing process. For example, every disposable needle and syringe,

Fig. 30.2 A silicone gel-filled breast implant (Mentor).

as well as intravenous tubing, is lubricated with silicone. Medications in stoppered vials contain residual silicone from its use in the manufacturing process. Silicone elastomers, in their solid form, are used for pacemaker coatings, tubing, prosthetic joints, hydrocephalus shunts, and various facial and penile implants. Like breast implants, some testicular and chin implants are made of a silicone gel in a silicone envelope.

Silicones are also found in some medications. If a medication contains an ingredient with the name “methicone” (e.g., simethicone), this is a silicone that has been modified for human consumption. Silicones are also used in household items such as lipstick, suntan/hand lotion, hairspray, processed foods, and chewing gum. Medical-grade silicones invoke a nonspecific foreign-body response, resulting in typical macrophage invasion, giant cell formation, and eventual scarring.¹⁶

Extensive investigations by several prestigious scientific bodies (e.g., the IOM,^{17,18} and the UK Department of Health¹⁹) have failed to show that systemic illness is definitively attributed to silicones. However, in January of 2011, the FDA, based upon a series of case reports which followed the sentinel case reported in 1997,²⁰ issued a safety communication stating, “women with breast implants may have a very small but increased risk of developing anaplastic large cell lymphoma (ALCL) in the scar capsule adjacent to the implant”.^{21,22} At the time of the communication, the FDA was aware of approximately 60 cases of breast implant patients who had developed ALCL out of the approximately 5–10 million women who had received breast implants worldwide. Since then over 200 women worldwide have been diagnosed with breast implant-associated ALCL (BI-ALCL). The exact cause and mechanism of BI-ALCL is unknown but is not limited to women with silicone-filled implants as women with saline filled implants have also developed the disease.^{23,24} For more details about BI-ALCL the reader is referred to Volume 5, Chapter 12.

The next progression in silicone gel breast implants was the approval by the FDA of cohesive gel implants (commonly referred to as “gummy-bear” implants). All three breast implant manufacturing companies have received approval for their cohesive gel implants, Sientra (Santa Barbara, CA) in March 2012; Allergan (Irvine, CA) in February 2013; and Mentor (Irvine, CA) in June 2013.²⁵

Polytetrafluoroethylene

Polytetrafluoroethylene (PTFE), also known as Teflon, was accidentally invented by Roy Plunkett in 1938 while he was trying to develop a refrigerant.²⁶ It consists of a carbon backbone with fluorine side chains. Expanded PTFE (ePTFE or Gore-Tex) was created by Bob Gore in 1969 when he rapidly stretched PTFE. It is very stable chemically, cannot be cross-linked (which makes it flexible), and has a nonadherent surface. When made with a pore size of 10–30 μm it will allow some limited tissue ingrowth. It has been used for a wide variety of applications, from hiking boots to coatings on frying pans. Within the medical field it is used for vascular grafts, mesh for abdominal wall reconstruction, and implants for facial augmentation.²⁷ The nonadhesive properties of ePTFE have been employed in surgical meshes used for hernia repair to reduce repair site adhesion. However, there are

significant limitations of ePTFE mesh used for hernia repair, including infection often requiring explantation and limited incorporation strength to the surrounding fascial edge compound to macroporous meshes such as polypropylene.

Polyester

Polyester contains an ester functional group in its main chain. Mersilene is a polyester fiber mesh knitted product for use in herniorrhaphy. Polyester mesh is softer and more hydrophilic than polypropylene, and in animal studies has shown better tissue ingrowth. Dacron is another form of polyester that has been used for vascular grafts.

Polypropylene

Polypropylene, or polypropylene, has a carbon backbone and side chains of hydrogen and methyl groups. It has been used in hernia and pelvic organ prolapse repair and is rarely rejected. However, polypropylene mesh can erode through the soft tissues over time. Therefore, the FDA has issued warnings on the use of polypropylene mesh in pelvic organ prolapse, specifically when in close proximity to the vaginal wall secondary to the number of mesh erosions reported by patients over the past few years.²⁸ It is also used as suture material because of its strength and low foreign-body reaction within the body. Knitted polypropylene surgical meshes are commonly used for hernia repair owing to a high ultimate tensile strength of the mesh and strong fibrovascular incorporation into the fascial defect edge. Direct placement over abdominal viscera can cause dense adhesions, fistula, and erosion. Reoperation through a polypropylene mesh hernia repair is often challenging due to this generalized fibrotic scarring to adjacent intraperitoneal viscera.

Polyethylene

Polyethylene consists of a carbon backbone with hydrogen side chains (ethylene). A high-density porous form of polyethylene (Medpor) is used for facial implants (Fig. 30.3). The

Fig. 30.3 Medpor (high-density porous form of polyethylene) implants used in facial augmentation.

porosity allows for tissue and vascular ingrowth. It can also be carved to customize the implant for individual patients. The implants are firmer and stiffer than the ePTFE implants and, because of the size of the pores, are more difficult to place because the soft tissues adhere to it more readily. In addition, the soft-tissue ingrowth makes the implant more difficult to remove. Porous polyethylene alone or with titanium mesh embedded within it is available for reconstruction of the orbital floor. One of the disadvantages of the polyethylene alone for orbital floor reconstruction is that the implant does not show up well on CT, making it difficult to diagnose a malpositioned implant.

Biodegradable polymers

Biodegradable polymers were developed to try to overcome some of the disadvantages associated with permanent implants. Most biodegradation begins through a chemical reaction such as hydrolysis or oxidation and involves some sort of biological process (e.g., enzymatic or cellular process) to eliminate the material completely. In addition to the requirement that the material itself must be biocompatible, all of the breakdown products of the material must be biocompatible as well.²⁹

Although there are a multitude of materials that will degrade *in vivo*, there are only a few that are clinically relevant as biodegradable polymers. Most of these are α -hydroxy acids, specifically poly(lactic acid) (PLA), poly(glycolic acid) (PGA) and combinations, or copolymers, of these individual polymers know as poly(lactic-co-glycolic acid) (PLGA). These polymers degrade through hydrolysis, ending in lactic or glycolic acid, a common byproduct of normal biochemical pathways.

Most surgeons are familiar with this polymer as it is the polymer used to make Vicryl (polyglactin 910; Ethicon, Somerville, NJ). These polymers have also been used to create biodegradable mesh for use in abdominal wall reconstruction and plating systems for craniofacial or hand applications.

Altering the ratios of lactic to glycolic acid or adding carbon fibers or other polymers can modify the rate of degradation. In general, increasing the concentration of lactic acid decreases the rate of degradation (i.e., the polymer lasts longer). In the past 15 years manufacturers have used these polymers to develop biodegradable plates and screws for craniofacial and hand applications. Each manufacturer has modified the ratio of lactic and glycolic acid as well as the specific manufacturing protocol to optimize the degradation rate and strength of the polymer. For example, LactoSorb (Biomet, Warsaw, IN) consists of 82% PLA and 18% PGA while Resorb X (KLS Martin, Jacksonville, FL; used in SonicWeld) is 100% poly D,L-lactic acid (PDLLA). At implantation, their strength is equal to that of titanium plating and decreases with time. Typically the structural integrity is preserved for the first 8 weeks to allow for bony healing to occur.

Vicryl knitted meshes are used as a temporary abdominofascial closure in complex abdominal wall reconstruction, particularly in a contaminated wound. The mesh helps contain the viscera initially and subsequently resolves, creating an iatrogenic hernia that is repaired in a delayed stage.

Ceramics

People have been using ceramic materials for thousands of years. However, medical applications of ceramics were not developed until the 1960s. Of the many ceramics available, only a few have been found to be suitable for implantation in humans. Ceramics have a crystalline structure and are made up of inorganic, nonmetallic molecules whose individual electrons are strongly bound to each individual atom (called heteropolar bonding; in contrast, homopolar bonding, seen in metals, allows the electrons to flow freely between atoms). The manufacturing of ceramic materials is achieved through a process called sintering, which requires the material to be fused together under high pressure and temperature. Ceramics have appealing physical properties for biomedical use, including decreased foreign-body response, resisting bacterial colonization, a high compressive strength, and tissue ingrowth into porous materials (100 μm pore size for bone and 30 μm pore size for soft tissue). However, their benefits are overshadowed by their weaknesses; namely they are brittle and fracture easily under tensile, torsional, or bending loads. Their main uses in plastic surgery are for bone augmentation and replacement.

Calcium phosphates are the most common ceramics used in plastic surgery. In addition, calcium phosphates have been shown in the laboratory to be both osteoinductive and osteoconductive, but this has not been demonstrated in the clinical setting.

Calcium phosphates come in two formulations for medical use: hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$) and tricalcium phosphate ($\text{Ca}_3(\text{PO}_4)_2$). Tricalcium phosphate has a faster rate of resorption and replacement by bone when compared to hydroxyapatite. They are available as granules for injection, blocks, both solid and porous, and the hydroxyapatite is also available as a cement paste. These implants are commonly used to reconstruct nonload-bearing bones of the face and cranium. The cement paste is beneficial in select cases, such as cranioplasty, because it is malleable and can be molded during the case.

Adhesives and glues

The first fibrin tissue adhesive was described in 1944 and was used to aid in the adherence of skin grafts to the recipient tissue bed. The first commercially manufactured fibrin sealant became available in 1978. Cyanoacrylate was synthesized in 1949 but this early product created a severe foreign-body reaction. Through chemical modifications to molecule, engineers were able to decrease the foreign-body reaction and create a clinically relevant product. There are several tissue adhesives available for clinical use. Most commonly, these adhesives are used to seal two tissues together or to provide hemostasis. Many of the adhesives possess both properties. Ideally, tissue adhesives should possess five characteristics (Box 30.2). Several classes of tissue adhesive are available and each will be discussed in the next sections.³⁰

Platelet gels

Platelet gels are derived from platelet-rich plasma (PRP). The starting material is 70 mL of whole blood that undergoes

BOX 30.2 Characteristics of the ideal tissue adhesive

- Must be safe (i.e., no allergic response, disease transmission)
- Must eliminate potential spaces
- Must be easy to use
- Must be cost-effective
- Must have a clinical benefit

centrifugation. The platelet layer, which also contains native fibrinogen, is then combined with bovine thrombin, resulting in a gel adhesive. This product is good for individuals who do not want to use the commercially available fibrin sealant. It is also less expensive to manufacture (once the initial equipment is accounted for) than the commercially produced fibrin sealants. There are, however, some drawbacks to this product. The concentration of fibrinogen in PRP is significantly lower than in the commercially available fibrin sealants. Thus, the PRP is a less effective adhesive. In addition, the tensile strength and hemostatic capabilities of PRP are also lower than the commercially available products. The clinical applications of this product include brow lift, facelift, abdominoplasty, the latissimus dorsi donor site, and deep inferior epigastric perforator/transverse rectus abdominis myocutaneous flap donor sites, where there is a large surface area that the surgeon would like to adhere together. Spray or mist applicators provide the best delivery method.

Fibrin tissue adhesives

Fibrin sealants were the first FDA-approved tissue adhesives and consist of two parts: fibrinogen and thrombin. A small amount of factor XIII and calcium is included to catalyze the reaction and form polymerized fibrin. Screened donors provide pooled human plasma as the source of the two ingredients. The commercially available product also contains an antifibrinolytic to decrease degradation and bovine-derived aprotinin, which acts as a stabilizer. In order to prevent disease transmission, the products undergo heat pasteurization and ultrafiltration.

The product must be refrigerated and requires approximately 20 minutes to prepare. The two bottles need to be placed in a special warmer for several minutes. Once heated, the components are drawn up into individual syringes. The dual syringe delivery system is designed to mix the two ingredients immediately before they are applied. There are multiple delivery mechanisms available. The simplest delivery system is a straight blunt-tipped needle. There are also sprayer/mister applicators and applicators for endoscopic use. The misters provide the maximal mixing of the two components and produce the thinnest layer of polymerized fibrin to the wound, which has been shown to have the strongest adhesive properties.³¹

The strength of the fibrin glue is directly proportional to the concentration of fibrinogen in the mixture while the rate of polymerization is regulated by the concentration of the thrombin. Thus, in applications where the tissues need to be manipulated (e.g., a large flap), a lower concentration of thrombin should be used. Plastic surgery applications for fibrin sealants are similar to the indications for PRP described

above. Fibrin sealants have also been used successfully to treat chronic seromas with percutaneous injection.³²

Cyanoacrylate

The original cyanoacrylates were butyl-cyanoacrylate. The butyl-cyanoacrylate is a short chain with rapid breakdown, which resulted in many wounds dehiscing. In addition, the breakdown products (formaldehyde and cyanoacetate) can cause a severe inflammatory reaction if butyl-cyanoacrylate penetrates the skin. In order to address these issues, octyl-cyanoacrylates were developed. They have longer side chains, creating a stronger and longer-lasting polymer. The polymerization begins when the 2-octyl-cyanoacrylate is exposed to moisture (there is enough moisture in the air to allow polymerization to occur). Applications in plastic surgery are limited to skin closure. Because the superficial layer of the skin, where the product is applied, will not have any sutures to hold it together, it is important to make sure the deep layers are well approximated and provide a tension-free abutment of the two sides. Studies that have been done comparing traditional suturing to using octyl-2-cyanoacrylate showed that the outcomes were equivalent.³³

Skin substitutes

Over the past 25 years, bioengineered skin substitutes have become a mainstream therapy for wound management.³⁴ Originally designed to replace skin grafts for patients with severe burns, their use has broadened to include the treatment of chronic venous and chronic diabetic ulcers. As these technologies continue to advance, their application will broaden even further (Box 30.3).

Although the ideal skin substitute does not exist, engineers and scientists have developed, and continue to refine, several very useful products. The engineering of cultured skin substitutes has been developed on the premise that three important components are required for their formation: (1) a cell source; (2) a “tissue differentiation-inducing” substance; and (3) a matrix.³⁵ A variety of cells, mediators, and polymers have been tested in various combinations to engineer cultured skin substitutes. We review the most common of these below and compare them in Table 30.3.

Integra

Integra (Integra LifeSciences, Plainsboro, NJ) is a bilayer skin substitute. The “dermal” (lower) layer is a bovine collagen

BOX 30.3 Characteristics of an ideal skin substitute

- Adhere to the wound bed rapidly
- Recapitulate the physiologic and mechanical properties of normal skin
- Be inexpensive
- Avoid immune rejection by the host
- Be highly effective in accelerating tissue regeneration and wound repair.

Table 30.3 Comparison of commercially available skin substitutes

Product	Company	Tissue of origin	Layers	Uses
Integra	Integra Life Sciences Plainsboro, NJ	Synthetic	1. Silicone 2. Collagen and GAG matrix	Deep- or full-thickness soft-tissue defects for coverage Requires skin graft
Epicel	Vericel Corp. Cambridge, MA	Autogenous	Cultured autogenous keratinocytes	Deep partial- and full-thickness burns >30% TBSA
Dermagraft	Organogenesis Canton, MA	Allogeneic dermis	Vicryl seeded with neonatal fibroblasts	Chronic wounds Full-thickness burns with STSG
Apligraf	Organogenesis Canton, MA	Allogeneic composite	1. Neonatal keratinocytes 2. Collagen seeded with neonatal fibroblasts	Chronic wounds Excision sites Used with STSG to improve function/cosmesis
AlloDerm	LifeCell Branchburg, NJ	Allogeneic dermis	Acellular dermis	Deep partial- and full- thickness burns Soft-tissue replacement Suspensory materials Interpositional grafts Tissue patches

GAG, glycosaminoglycan; STSG, split-thickness skin graft; TBSA, total body surface area.

(Adapted from Shores JT, Gabriel A, Gupta S. Skin substitutes and alternatives: a review. *Adv Skin Wound Care*. 2007;20:493–508; quiz 509–510.)

base with glycosaminoglycan chondroitin-6-sulfate while the upper layer is a silicone sheet that acts as a temporary epidermis.³⁶ As the wound heals the dermal layer is replaced with the patient's own cells.³⁷ A thin split-thickness skin graft is then applied on to the neodermis. Integra is indicated for the management of complex wounds such as partial- or full-thickness burns, and multiple types of ulcer. Several studies have evaluated the efficacy of Integra and have compared Integra with autograft, allograft, xenograft or Biobrane. Biobrane (Smith & Nephew, Largo, FL) is a biosynthetic dressing constructed of a silicone film with a collagen-bound nylon fabric partially embedded into the film. These studies showed that Integra has a higher rate of infection than the other tested product with regard to wound infection and graft take. However, Integra appeared to be better than autograft, allograft, or xenograft in terms of wound-healing time. Integra is also used in complex wounds to which a skin graft would not adhere.^{36,38,39} The neodermis attaches to the underlying bed, vascularizes over 10–14 days, and then provides a surface for a split-thickness skin graft to adhere to.

Epicel (cultured epidermal autografts)

Epicel (Vericel Corp., Cambridge, MA) is a cultured epidermal autograft grown from the patient's own keratinocytes. A small skin biopsy is harvested from the patient and sent to the company for processing. The keratinocytes are grown in a co-culture using proliferation-arrested, 3T3 murine fibroblast feeder cells. Once the keratinocytes are 2–8 cell layers thick the autograft is returned to the patient for grafting. The graft is attached to petrolatum gauze backing with stainless steel surgical clips and measures approximately 50 cm².

Epicel is indicated for patients who have either deep dermal or full-thickness burns involving a total body surface area of greater than or equal to 30%. It can be used in conjunction with split-thickness skin grafts, or alone in patients for whom split-thickness skin grafts may not be an option due to the severity and extent of their burns. Epithelial cells have been

combined with Integra to regenerate skin and oral mucosa successfully in animal models. This has been performed with cultured epidermal autograft placed over vascularized Integra,⁴⁰ preseeded keratinocytes into the Integra, and applied in a single stage.^{41–44}

Dermagraft

Dermagraft (Organogenesis, Canton, MA) is a polyglactin mesh seeded with neonatal fibroblasts. The fibroblasts produce collagen, glycosaminoglycans, fibronectin, and other growth factors. Over time the mesh is resorbed and replaced with the patient's own tissue.³⁷ Dermagraft has applications as both a temporary and permanent covering to increase the successful take of meshed split-thickness skin grafts on excised burn wounds and for venous ulcers and pressure ulcers.^{37,45} With respect to infection, exudate, healing time, time to closure, and graft take, Dermagraft has been shown to be equivalent to allograft.^{45–47}

Apligraf

Apligraf (Organogenesis, Canton, MA) is a bilayered skin-equivalent. The lower "dermal" layer consists of type I bovine collagen and fibroblasts obtained from neonatal foreskin. The upper "epidermal" layer is derived from keratinocytes. It has to be applied "fresh" and has a shelf-life of 5 days at room temperature.³⁷ It has been used to cover and help heal venous ulcers and diabetic foot ulcers. It has been used as a temporary covering over meshed expanded autograft for excised burn wounds.⁴⁸

Bioprosthetic mesh

To avoid the possible side effects of synthetic prosthetic mesh and provide a more biocompatible material, bioprosthetic materials have been developed and used for multiple

BOX 30.4 Characteristics of the ideal bioprosthetic mesh

Resistance to bacterial colonization and chronic infection

Biocompatibility and noncarcinogenicity

Available readily at acceptable cost

Ability to withstand physiological stresses over a long period of time

No additional pain caused after implantation

Promotion of strong tissue ingrowth

Avoidance of substantial contraction or expansion after implementation

Limits development of adhesions to visceral structures induced

Provides cells with a supportive framework and the necessary signals for host cells to grow, differentiate, and interact, while at the same time it should become remodeled as the wound gains strength and new tissue is formed

(Adapted from Bellows CF, Alder A, Helton WS. Abdominal wall reconstruction using biological tissue grafts: present status and future opportunities. *Exp Rev Med Devices*. 2006;3:657–675.)

applications. Currently available bioprosthetic mesh materials are derived from decellularized mammalian tissues, either human (allogeneic) or animal (xenogeneic). Dermis is the most common source tissue for bioprosthetic meshes. Bioprosthetic mesh materials are processed to remove cells, cellular debris, and other potentially immunogenic components optimally without disrupting the native extracellular matrix (e.g., collagen, proteoglycan) architecture. Preservation of the native extracellular matrix is important to allow these materials to remodel and regenerate (gradually being replaced with native host tissue) rather than become scarred and encapsulated by the body. An ideal mesh should possess the characteristics shown in [Box 30.4](#).

There are a growing number of bioprosthetic mesh materials available from which the surgeon can select. Many of these materials are used for complex torso reconstruction, including breast reconstruction, chest wall reconstruction and ventral hernia repair.⁴⁹ They are often selected over synthetic mesh owing to their ability to resist infection.⁵⁰ They limit repair site adhesions^{51,52} and tolerate cutaneous exposure, usually without the need to remove the bioprosthetic mesh.

Small intestinal submucosa

Small intestinal submucosa (SIS) (Biodesign, Cook Biotech, West Lafayette, IN) is a biomaterial created from the small intestine of pigs. After removal of the mucosal, serosal, and muscular layers of the small intestine, a strong, collagenous matrix remains. The submucosa of the small intestine provides mechanical strength to the intestine. The strong, yet biochemically rich and diverse extracellular matrix of the submucosa makes it an excellent choice for a naturally derived biomaterial. First described as a vascular graft in 1989,⁵³ SIS has been applied to over 20 applications in humans, including multiple types of hernia repair,^{54–56} dural repair,⁵⁷ bladder reconstruction,^{58,59} and stress urinary incontinence treatment.⁶⁰ Originally released in 1989 as Surgisis, this biomaterial has undergone several revisions to allow better integration of the host tissue. In 2008, it was renamed

Biodesign to reflect the significant improvements that had been made to the biomaterial.

Human acellular dermal matrix

Human acellular dermal matrix (HADM) (AlloDerm, LifeCell, Branchburg, NJ; Allomax, Bard Davol, Murray Hill, NJ; and FlexHD, Ethicon360, Somerville, NJ) is made from donated allograft human dermis. Each manufacturer has a proprietary technique for producing the acellular dermal matrix. In general the epidermis and subcutaneous tissue are removed and the dermis is processed, with either freeze-drying or chemical detergents, resulting in the collagen structure of the dermal matrix. Applications of HADM include implant-based breast, abdominal wall, chest wall, and pelvis reconstruction, and lip augmentation. Micronized HADM (Cymetra, LifeCell, Branchburg, NJ) is also available and has been used for laryngoplasty and as a soft-tissue filler.

Porcine acellular dermal matrix

Porcine acellular dermal matrix (PADM) has been developed for applications similar to HADM. Porcine materials are more abundant and it is easier to control the harvesting conditions. However, because the PADM is from a xenogeneic source, additional processing must occur to prevent an adverse immunogenic reaction when implanted in humans. To inhibit immunogenicity and reduce collagenase-dependent matrix degradation, first-generation PADM (CollaMend, Davol Bard, Warwick, RI and Permacol, Covidien-Medtronic, Minneapolis, MN) undergo intentional chemical cross-linking of collagen fibers during the manufacturing process. A secondary side effect of the cross-linking is the alteration of the extracellular matrix structure, which has been shown to inhibit cellular infiltration, revascularization, and matrix remodeling potential.⁶¹

A newer generation of PADM (Strattice, LifeCell, Branchburg, NJ), is processed without chemical cross-linking. In this case, the [galactose- α (1,3)-galactose] antigen, which is the major cause of the immune response associated with acellular xenografts, is enzymatically removed.

It is not entirely clear which of these products has a better outcome; however, in a recent *in vivo* animal study comparing cross-linked PADM to noncross-linked PADM for abdominal wall reconstruction, the noncross-linked PADM was rapidly infiltrated with host cells and vessels while cross-linked PADM became encapsulated. Noncross-linked PADM had weaker adhesions to repair sites while it increased the mechanical strength of the bioprosthesis-musculofascia interface at early timepoints. Thus, the study concluded that noncross-linked PADM may have early clinical advantages over cross-linked PADM for bioprosthetic abdominal wall reconstruction.⁶² However, no comparative human studies have been performed to date.

Other bioprosthetic mesh products

Bovine pericardium (Veritas, Baxter Healthcare Corp., Deerfield, IL) collagen matrix is a noncross-linked bovine pericardium. The decellularization and reduction of the immunogenicity are achieved by capping free amine groups using a proprietary chemical process.

Bovine fetal dermis (Surgimend and Primatrix, Integra Life Sciences (formerly TEI), Plainsboro, NJ) is an acellular dermal matrix derived from fetal calves. It is not cross-linked and can facilitate cell penetration, revascularization, and integration with host tissues.

Amniotic/placental-based materials

Amnion has been used as a biomaterial for over 100 years. Its first published use as a skin graft occurred in 1910 and its first use in burn patients in 1912.^{63–65} The amniotic membrane is a monolayer of epithelial cells, a thick basement membrane, and an avascular matrix. This epithelium manufactures multiple cytokines and growth factors. The amnion has been reported to promote epithelialization while maintaining antimicrobial, immunogenicity, and analgesic properties. Many of the properties are preserved even after de-epithelialization and sterilization of the amnion. Due to these factors, amnion has biological and mechanical properties that make it useful as a valuable dressing material.^{63,66} Over the past few years several companies have developed products derived from either human placental, amniotic or chorionic tissue. BioFix (Integra LifeSciences, Plainsboro, NJ) and AmnioFix (MiMedx, Marietta, GA) are sterile, dehydrated and decellularized amniotic membrane. They are used to cover wounds and to fill tissue defects. BioFix Plus (Integra LifeSciences, Plainsboro, NJ) and EpiFix (MiMedx, Marietta, GA) are similar products but these also include the chorion. These products require no preparation and can be placed on the wound with either side up. One of these companies has also released a particulate human decellularized placental connective tissue matrix (BioFix Flow, Integra LifeSciences, Plainsboro, NJ). This product comes in a syringe and is designed to

be used as an injectable connective tissue matrix. All of these products are stored at room temperature with a 5-year shelf-life. Grafix (Osiris Therapeutics, Columbia, MD) is a cryopreserved placental membrane, which, like the products mentioned above, is made up of extracellular matrix and growth factors/cytokines. However, this product also contains cells native to the tissue (which include epithelial cells, fibroblasts, and stem cells). It is used to help heal wounds. As it is a frozen product, it needs to be thawed prior to being used.

Future materials

Biomaterials and implants have made huge impacts on medicine and surgery. Some implants are designed to have as little impact or interaction with the body as possible. Others are designed to interact with the body in a passive way (e.g., biodegradable PLGA polymers). The most recent biomaterials are being designed to modulate their environment to create a tissue-specific response. Furthermore, hybrid biomaterials containing cells, polymers, and growth factors are currently being developed in *in vivo* models. These biomaterials will eventually be able to “sense” their surroundings and change their biochemical and mechanical properties in response to the needs of the environment. As with the past development of biomaterials, the continued progress of the biomaterial field depends upon an interdisciplinary collaboration between engineers, scientists, clinicians, and industry. With continued cooperation between these biomaterials experts, the future use of biomaterials and implants in plastic surgery will likely change significantly in the future. The goal would be to manufacture materials with specific properties to reconstruct site-specific defects individualized to the exact biologic, chemical, and functional needs of the reconstruction.

SYNOPSIS

- The success of osseointegration biotechnology has revolutionized facial prosthetic reconstruction.
- Titanium is the implant material of choice as it is light, biocompatible, and resistant to corrosion.
- Implant placement technique is crucial to produce bone–implant contact with no interposed fibrous tissue and successful bone healing.
- Appropriate treatment selection requires understanding of all options available.
- Multidisciplinary team planning is required.
- Osseointegration biotechnology provides plastic surgeons with more treatment options for challenging head and neck deformities.

Deformities in the head and neck region can have a profound effect on the function, aesthetics, and psyche of an individual. Considerable time, effort, and ingenuity have been spent trying to develop meaningful reconstructive solutions to a wide variety of craniofacial defects. Autogenous reconstruction remains the gold standard, but in certain cases, autogenous reconstruction may be contraindicated, technically impossible, or have the potential to solve the reconstructive issues only partially.

Historically facial prosthetics have been of limited benefit. Retention of facial prostheses has been largely unsuccessful because of the need for adhesives or crude mechanical means of maintaining retention. The patient lacked confidence about the positioning of the prosthesis and its ability to stay in place. Often associated pain or discomfort would limit the length of time and circumstances in which the prosthesis would actually be worn. The adhesives are those used in industry and were not developed for the unique sensitive human biological environment. They often had adverse effects on the underlying skin compromised by radiotherapy, trauma, or thermal injury¹ and affected the durability and longevity of the prosthesis.

With the success of osseointegration and its ability to solve the problem of prosthetic retention,^{2,3} a new treatment

modality was now available.^{4,5} Prosthetic longevity is increased without the need for adhesives.^{6,7} Osseointegrated facial prosthetics now meet the necessary criteria for success: (1) aesthetic acceptability; (2) functional performance; (3) biocompatibility; and (4) desired retention.⁸ The use of osseointegration biotechnology in facial prosthetic restoration has been hailed as the most significant advance in the field of facial prosthetics in the past 28 years.⁹ It is estimated that more than 90 000 implants have been installed extraorally in more than 45 000 patients up to the year 2007.¹⁰ Craniofacial osseointegrated reconstruction gives the plastic surgeon another viable treatment option in many challenging head and neck defects.¹¹ It can provide some patients with a meaningful and enhanced quality of life when in the past other treatment options would not have been successful. Unfortunately, competing specialties or providers have presented autologous techniques and craniofacial osseointegration as unrelated technologies.¹² Osseointegrated and autogenous techniques should not be viewed as competing technologies, but rather as complementary reconstructive procedures that optimize the opportunity for success in the management of major head and neck deformities.

Why this situation has arisen is unclear. In some cases, it appears to be due to a lack of understanding of osseointegration and its benefits. It may be viewed only as a salvage procedure when all else has failed and both the patient and surgeon are desperate. It is not viewed as “real” surgery, only as throwing a few screws in the bone. Those in doubt cannot understand how patients would be satisfied with a prosthesis, “a foreign object that never becomes part of their body image”. To any surgeon with experience in osseointegration, these lines of thinking are seriously flawed.

This intervention requires long-term support by both the caregiver and the funder for maintenance of the implant sites as well as future prosthetic construction. It is analogous to the time and financial commitment required in an organ transplantation program.

Historical perspective

Historically, implants in bone were largely unsuccessful and had a poor reputation for long-term success. In the 1950s, Professor Brånemark, from Goteborg, Sweden, discovered titanium behaved somewhat differently from other metals when in contact with bone. The term “osseointegration” was coined by Brånemark in 1977.¹³ It is defined as the direct contact – structural and functional – between ordered living bone and the surface of a load-bearing implant. Osseointegration is a dynamic process that involves micromodeling at periosteal and endosteal surfaces and remodeling at the bone–implant interface.^{8,10,14} This principle of osseointegration ultimately led to the development of successful dental implants.¹⁵ The first osseointegrated implant was placed in a human in 1965. Albrektsson *et al.* further postulated that a skin-penetrating implant may be possible.¹⁶ Implants were first placed in the mastoid region to support a bone-anchored hearing aid in 1977 and to retain an auricular prosthesis in 1979¹⁷ (Fig. 31.1). Subsequently, numerous reports have confirmed the efficacy and predictability of craniofacial osseointegration.^{18,19} The concept of anchoring craniofacial prostheses on osseointegrated implants was accepted by the Food and Drug Administration (FDA) in 1985. The FDA accepted the concept of anchoring hearing aids on implants in adults in

1995 and children in 1998. In 1985, implants were used in hand surgery to anchor joint replacements and in the early 1990s the concept was used for anchoring prostheses in amputees’ fingers, hands, arms, and legs.

Fig. 31.1 Historical development of osseointegration biotechnology. Through the Brånemark experience, osseointegrated implants have been subjected to over 30 years of scientific scrutiny. Craniofacial applications were first introduced in 1977. EO, extraoral.

BOX 31.1 Advantages of craniofacial osseointegration⁷

Procedures short
 Minimal morbidity
 Minimal postoperative pain
 Outpatient procedures
 Short learning curve
 Allows examination of tumor resection site
 Salvage of autogenous failures
 Use in compromised tissues
 Excellent prosthetic aesthetics

BOX 31.2 Disadvantages of craniofacial osseointegration⁷

Need for multidisciplinary team
 Need for reliable, committed patient
 Ongoing expense of prosthetic remakes and maintenance visits
 Not one's own tissue

Access the Historical Perspective section and Fig. 31.1 online at

Advantages of craniofacial osseointegration

Craniofacial osseointegration has many advantages (Box 31.1).²⁰ The surgical procedures are generally short with minimal morbidity and are performed on an outpatient basis. There is a short learning curve and results are predictable. The patients usually have minimal postoperative discomfort. Examination of the tumor resection site is easy and allows early diagnosis of any tumor recurrence.

Craniofacial osseointegration can successfully salvage a patient with a failed autogenous reconstruction and often offers superior aesthetics. When compared with adhesive-retained facial prosthetics, osseointegration offers predictable prosthetic retention, increased prosthetic durability and lifespan, enhanced prosthetic aesthetics, ease of displacement, no underlying skin damage, successful incorporation of the prosthesis into the body image, and a happier, more satisfied patient. Osseointegration can also be considered in diabetics and smokers.

The disadvantages of craniofacial osseointegration include the need for a larger multidisciplinary team with skills that are often not freely available. Patients also require regular maintenance visits and a new prosthesis every 2–5 years (Box 31.2).²⁰ Lifetime ongoing costs can be an issue with some insurance companies.

Indications for craniofacial osseointegration

Craniofacial osseointegration can be of particular benefit for reconstruction of selected defects involving the ear, orbit, nose, and combined midfacial defects. The osseointegrated implants have also been used to secure hairpieces.²¹ A newer application of interest to the plastic surgeon is the use of a bone-anchored hearing aid (BAHA) in children with microtia. In the past concern has been expressed combining a BAHA and an autogenous ear reconstruction. Fear of inappropriate positioning of the implant adversely affecting future autogenous ear reconstruction usually prevented patients having the benefits of both treatment modalities. This usually resulted in the BAHA being placed too far posterior or not being considered at all. Certainly the BAHA is an excellent option for hearing restoration in bilateral microtia patients and more recently has proven of benefit in unilateral microtia patients (Fig. 31.2). It is a much more straightforward, safe, and predictable way of improving hearing than previous autogenous means of canalplasty and middle-ear reconstruction.¹⁰

Ear reconstruction

Autogenous reconstruction of auricular defects has improved greatly in the latter half of the 20th century because of the work of pioneers such as Tanzer,²² Brent,^{23–26} Fukada and Yamada,²⁷ Cronin,²⁸ Bauer,²⁹ Yanai *et al.*,³⁰ Isshiki *et al.*,³¹ Nagata,^{32–34} and others. Certainly, not all reconstructive attempts are successful. The appropriate treatment selection for major ear defects continues to be controversial (Table 31.1).²⁰ Certain auricular defects have limited autogenous

Fig. 31.2 Bone-anchored hearing aid (BAHA) and autogenous ear reconstruction for microtia.

Table 31.1 Indications for osseointegrated ear reconstruction ⁷	
Definitive	Relative
Major cancer resection	Microtia – most controversial
Radiotherapy	Absence of lower half of the ear
Severely compromised tissue	Calcified costal cartilage
Patient preference	
Failed autogenous reconstruction	
Potential craniofacial anomaly	
Poor operative risk

Failed autogenous reconstruction
Scarring at autogenous donor sites
Reconstruction following autogenous reconstruction because of tumor recurrence
Patient preference
Medical contraindication to multistaged autogenous reconstruction

options, particularly after removal of the ear for cancer with associated radiotherapy. It is our belief that these reconstructive techniques are complementary and must be presented in this manner.^{8,12,20} Definite indications for osseointegrated auricular prosthetic reconstruction include: (1) following major cancer resection; (2) radiotherapy to the proposed site of auricular reconstruction; (3) severely compromised local tissue (Fig. 31.3); (4) patient preference; and (5) salvage procedure for failed autogenous reconstruction. Relative indications include: (1) microtia; (2) absence of the lower half of the ear; and (3) patients with calcified costal cartilage.

Probably the most controversial indication for osseointegrated auricular reconstruction is microtia in children. Although it is technically possible to place implants in children as young as 3 years of age and early results are encouraging, the follow-up in these situations is short. Because the use of craniofacial osseointegrated implants requires removal of any local ear remnants and produces scarring in the operative field, future autogenous reconstruction options are very limited. For these reasons, the use of osseointegrated auricular reconstruction in the pediatric age group requires very careful consideration by the clinician and family (Fig. 31.4). A publication by Zeitoun *et al.*³⁵ outlines the difficulties seen using

osseointegration in the pediatric population. It also showed an increased need for psychological support in many of these patients. Our approach is to offer autogenous ear reconstruction to pediatric patients with microtia. Despite the potential for difficult treatment selection decisions, we rarely find this to be the case. Patients usually decide quite quickly after the possibilities are discussed. It is rare for patients to change their mind following further discussion.

The use of an adhesive-retained auricular prosthesis is very limited and almost relegated to historical significance only. It certainly cannot be considered a “test” for an osseointegrated prosthesis. It offers none of the major advantages of implant-retained prostheses such as ease of placement, predictable retention, improved aesthetics, increased lifespan of the prosthesis, and no ongoing insult to the skin.

Osseointegrated nasal reconstruction

Indications for osseointegrated nasal reconstruction include: (1) failed autogenous reconstruction; (2) significant scarring in potential autogenous donor sites;⁶ (3) tumor recurrence following initial autologous reconstruction; and (4) patient preference (Box 31.3). Because of the need for multiple

Fig. 31.3 (A–C) Reconstruction following severe electrical injury included cranioplasty, free-flap scalp coverage, and ear reconstruction with implant-retained prosthesis.

Fig. 31.4 (A,B) Ear loss and severe local tissue trauma secondary to dog attack in a child. Reconstructed with implant-retained prosthesis.

surgical stages and the greater variability in the ultimate result with autogenous reconstruction, many patients with total nasal loss opt for placement of implants and a nasal prosthesis (Fig. 31.5). Certainly, there is less surgery involved with less morbidity. There is no need for other donor sites, and tumor surveillance is easy with prosthesis removal.⁸ The application of “nontraditional” long zygomatic implants may be useful in difficult situations of nasal reconstruction.³⁶

Osseointegrated orbital reconstruction

Patients with loss of the orbit and orbital contents have very poor autogenous reconstructive options (Box 31.4). Although autogenous coverage may be necessary to cover important neurological structures, in many cases it is provided only to fill the residual orbital cavity. However, “filling the hole” does not create an aesthetic result. It is in these situations that

BOX 31.4 Indications for osseointegrated orbital reconstruction

- Loss of orbit and orbital contents
- Severe enophthalmos with compromised vision
- Difficulty with an ocular prosthesis and significant eyelid distortion secondary to trauma or radiotherapy that is not amenable to autogenous correction

osseointegrated orbital reconstruction clearly has advantages over autogenous reconstruction (Fig. 31.6). The aesthetic results are far superior and again allow visualization for early tumor recurrence. This approach could also be considered in patients with severe enophthalmos and significantly compromised vision. Less frequently, it can be considered in patients with an ocular prosthesis and significant eyelid distortion

Fig. 31.5 (A–D) Nasal deformity following cancer resection reconstructed with implant-retained nasal prosthesis.

Fig. 31.6 (A,B) This patient had an orbital exenteration for a neurofibroma of the orbit and scalp and was reconstructed with latissimus dorsi free flap and skin graft. Further reconstruction using an implant-retained orbital prosthesis achieved a more aesthetic result.

Fig. 31.7 (A,B) This patient had an extensive basal cell carcinoma invading his orbit, nasal region, and maxilla. After surgical extirpation, implants were later placed and a naso-orbital prosthesis constructed. Autogenous options were poor.

secondary to trauma or radiotherapy that is not amenable to autogenous correction. The hope for the future would be to create an orbital prosthesis that can mimic movement of both the lids and globe of the opposite normal eye.¹³

Midfacial reconstruction

Patients with complex facial defects that may include the orbit, nose, and maxilla again have poor autogenous options (Fig. 31.7). Craniofacial osseointegration offers significant advantages. It enables examination of the postsurgical

oncologic defect and allows for a very acceptable aesthetic result. In the patient shown in Fig. 31.7 it allowed early detection of a recurrence on the posterior orbital wall. Treatment consisted of surgical removal and reconstruction with a temporoparietal fascial flap and skin graft. The patient was able to resume wearing his prosthesis again only 12 days after surgery to resect the recurrence. Extraoral osseointegration in combination with intraoral osseointegration may also result in significantly improved functional results over conventional prosthetic or autogenous techniques.

In some cases the extent of resection, the nature of the reconstruction, and the quality and quantity of remaining bone or patient preference may make an implant retained prosthesis impractical or undesirable. Other means of retention may be used to hold a prosthesis in place with reasonable aesthetic and functional results (Fig. 31.8). This could also be a treatment alternative in a select group of patients being considered for composite tissue allotransplantation or as an interim measure prior to CTA.

Factors important to obtain osseointegration^{13,37}

Choice of implant material

Many materials have been considered for osseointegration. Although other metals such as vanadium, tantalum, aluminum hydroxide, and ceramics like hydroxyapatite are known to integrate with bone to a certain degree, titanium is currently the material of choice.³⁷ Titanium is relatively light but stiffer than bone. Its springiness allows it to flex with the bone. The most important factor is the ability of its

titanium oxide layer on the implant surface to react with the adjacent bone (its biocompatibility). The key to success is what happens at this implant–tissue interface. The most successful is commercially pure titanium, which is 99.75% pure. This differs from the most commonly used titanium alloy, which contains 90% titanium, 6% aluminum, and 4% vanadium, and exhibits much less satisfactory characteristics of osseointegration.

Implant–tissue interface

Except for mechanical forces, all interactions between the implant and host occur from physiochemical forces less than 1.0 mm from the surface. When the titanium implant is exposed to oxygen and comes in contact with the host, a layer of oxide is rapidly formed. It acts as a protective barrier and prevents direct contact between the metal and its environment. The titanium oxide layer continues to grow with time and creates a dynamic interface. The oxide layer is the bioactive component of the implant. The microsurface characteristics of the implant itself, including roughness, porosity, and thread design, all influence its potential for successful osseointegration. A surface roughness of 100 μm or greater is advantageous; an implant that has a very smooth surface will result in poor integration, but with minor bone resorption. A very rough surface will result in rapid integration, but secondary inflammation and resorption that can jeopardize integration later on.

The macrostructure of the implant has importance for integration. Rounding the outer edges and spaces of a threaded implant relieves stress concentration. A screw-shaped implant often shows good primary stability, whereas a cone-shaped implant might be lost because of initial micromovements and hence poor stability.

Fig. 31.8 (A,B) This patient had a recurrent basal cell carcinoma resulting in resection of both orbits and the anterior maxilla. After reconstruction with free fibular and radial forearm flaps, a facial prosthesis retained by anatomical undercuts and eyeglasses was created as the patient did not wish to proceed with osseointegration.

Fig. 31.9 Bone–titanium interface with only oxide layer and no interposed soft tissue.

Bone bed

The bone bed into which the implant is installed is of importance. There is a difference if the implant is installed in a child with relatively soft and immature bone, compared with an adult. The older patient with osteoporosis will integrate the implant to a lesser degree, and implant failure rates have been higher. Patients who have been irradiated or sustained burns will have an altered texture of bone that will reduce the capacity to integrate implants.

Bone preparation

Meticulous, gentle surgical technique is vital for osseointegration to occur.¹⁰ Bone preparation must result in new bone healing around the implant with no interposed fibrous tissue formation and minimal bone necrosis (Fig. 31.9). Proper bone healing results in bone ultimately being in intimate contact with the titanium oxide layer. Sharp drill bits, copious saline irrigation, and slower drilling speeds are required for success. Studies have shown temperatures of 89°C occurring with high-speed drilling despite cooling.^{38–40} Bone exposed to temperatures greater than 47°C for 1 minute showed decreased new bone formation. Exposure to 44°C showed no negative effect. The fixture should only be handled by titanium instruments and never touched by the gloved hand. It is further important that the surgical field should be protected from fibers, powder, and other substances that might hinder osseointegration. At the junction of the titanium oxide and bone, a layer of ground substance consisting of proteoglycans and glycosaminoglycans forms. The thickness of this layer is inversely related to the strength of integration of the bone with the implant.

Traumatic surgery and an implant bed of low healing potential are said to be primary factors limiting successful osseointegration. Implant mobility, overloading, and poor implant biocompatibility are considered to be secondary factors in failure of osseointegration. With successful osseointegration, the weakest portion of the osseointegrated bone–implant complex is the bone itself. After successful osseointegration, attempting to remove an implant will result in failure within the surrounding bone, not at the implant–bone interface.

Implant load

The load of the implant should preferably be in the longitudinal direction. It is important to avoid rotational or cantilever

forces once the implant has integrated. If forces are distributed in the longitudinal direction, even very high loads can be withstood by the implant during many years of function.

Treatment planning

Providing craniofacial osseointegration care requires a larger multidisciplinary team than autologous reconstruction. The core team should include appropriate surgical expertise, including plastic surgery, otolaryngology, and oral surgery, a prosthodontist, an anaplastologist, and appropriate nursing and dental assistants. Careful preoperative assessment and planning are crucial for the ultimate success of this clinical endeavor. Only by having the full spectrum of team members can the patient be presented with all appropriate options to make a truly informed decision.

The treatment-planning process starts with a multidisciplinary consultation. Team members then formulate an approach to each individual patient's problem. The preoperative workup includes charting, standardized preoperative photographs and psychological profile. Preoperative assessment allows an evaluation of bony sites for implant placement, the presence of surrounding vital structures, general quality of the bone, and overlying soft tissues. Radiologic examination, impressions of the defect and the corresponding normal side, and three-dimensional images may be used during digital treatment planning, medical modeling, and construction of surgical templates.^{41–43}

The patient should have no systemic or local factors that could significantly influence bone-remodeling capacity.⁴⁴ Age alone is not considered a contraindication. Patients as young as 3 years of age or in their 80s have been successfully treated. There should be no psychiatric or substance abuse conditions. Smoking is a relative contraindication,⁴⁵ as is radiotherapy,^{10,46,47} or chemotherapy.⁴⁸ The literature on smoking and implant survival involves dental implants and not craniofacial osseointegrated implants.⁴⁹ A past history of radiotherapy requires assessment for hyperbaric oxygen treatment before and after implant placement to optimize the chance for successful osseointegration.^{50–52} Patients must have a certain level of cognitive, visual, and dexterous ability to maintain osseointegrated implants. They must also have reasonable geographic accessibility to an osseointegration unit. Once the preoperative workup and informed consent have been obtained, treatment can begin.

In autologous reconstruction, the surgeon provides the final result. This differs from osseointegration, where the surgeon sets the stage for the final prosthetic result by the prosthodontist or anaplastologist. This makes preoperative planning and proper implant placement even more vital to ultimate treatment success. Good communication between the surgeon and prosthodontist or anaplastologist preoperatively and often intraoperatively is critical. Implants placed in the wrong position will compromise the final aesthetic and functional result or make further implant placement necessary.

Surgical technique

The surgical approach as developed by Brånemark is a meticulous multistep technique that may be performed in one or two stages, depending on the clinical situation.⁵³ Although

titanium is used by many specialties in many clinical situations, this application resulting in osseointegration should not be confused with these other uses of titanium. Osseointegration biotechnology is very specific in terms of osseointegration fixture production and preparation, surgical technique, and final surgical result. Other implant systems (Conexão, Otorix, Straumann, ITI, Southern) are available but are principally based on the original implant.¹⁰

Compared to intraoral osseointegration, the fixtures for extraoral use tend to be shorter (3–5 mm). The length of implant used depends on the particular bone thickness. Longer fixtures can sometimes be used in the frontal bone, zygoma, and maxilla. Ideally bicortical purchase is obtained if anatomically possible. The extraoral environment tends to be a more hostile, less forgiving environment than the protected intraoral situation. The gingiva is constructed to have mucosal penetration; saliva and the cleaning action of the tongue are quite beneficial in keeping the abutments clean. Penetration through skin with nearby hair, muscle, and sebaceous glands lends itself to the development of more soft-tissue problems. The skin does not attach to the implant abutment and is essentially maintained as an open wound. The ability to modulate this interface better would result in fewer local skin problems.

Surgery can be performed in one or two stages.^{1,12} The one-stage procedure is usually reserved for adult patients with good bone quality and quantity. The surgery can be performed either under general anesthesia or with sedation and local anesthesia.

A treatment template is used to locate the site for implant placement. Appropriate implant positioning is crucial to the ultimate prosthetic success. Digital technologies can be useful for this aspect of treatment planning. Adobe Photoshop or Geomagic Freeform have been used successfully for this purpose (Fig. 31.10). In ear reconstruction, implants should be placed under the future site of the antihelical fold of the ear prosthesis. This is where there is maximal depth to hide the protrusion of the fixture abutments within the prosthesis.

In orbital reconstruction, the implants need to be placed well within the orbital rim rather than anteriorly, where it is technically easier to place them. Again consideration needs to be given to the space requirements of the orbital prosthesis in all three dimensions. Within the orbit, the implant axes should not align to a central converging point because this may make prosthetic procedures very difficult.

In nasal reconstruction, better success is obtained by placing implants into the floor of the nose rather than into the glabellar region. In cases where there are concerns about the underlying bone quality or quantity, a radiological study will be performed (Fig. 31.11). Simplant or Mimics software in combination with a CT scan allows assessment of the bone and surgical simulation of implant placement. Appropriate templates can then be constructed to help the surgeon with the implant surgery.

At surgery the area is infiltrated with a lidocaine (Xylocaine) and epinephrine solution and a skin flap is elevated. The periosteum is exposed and either a periosteal flap is elevated or a circular opening made in the periosteum. A surgical locating template is invaluable in difficult cases to optimize positioning of the implant, minimize the extent of surgical dissection, decrease the number of pilot drill holes needed to find adequate bone, and decrease the duration of the procedure. A 3.0-mm guide drill is used first. If bone is present at this depth after drilling, the drill hole is deepened to 4.0 mm. This drilling is carried out at a speed of 2000 rpm with copious saline irrigation. The base of the guide hole is checked to determine that penetration of underlying vital structures has not occurred.

In the second step, the guide hole is widened with a countersink. A fresh countersink drill is used with copious saline irrigation. This also prepares a flat countersink area on the bony surface for seating of the implant flange. Flangeless fixtures are often placed in the orbital region. Issues with cleaning and accumulation of debris around the implant flange can be problematic and threaten long-term survival of the implant.

The third step involves placing the self-tapping implant. It is placed at a drill speed of 15–20 rpm and 20–40 N-cm torque. All these precautions are taken to minimize bone necrosis. With bone necrosis, fibrous tissue will develop, compromising the tissue–implant interface, and osseointegration will not occur. All drills and countersinks are discarded after each procedure. Craniofacial implants are 3.75 mm in diameter and are available in 3.0, 4.0, and 5.5-mm lengths (Fig. 31.12). The longest implant possible is preferable based on bone depth and quality.

At the fourth step, a cover screw or space screw is placed in the implant. This prevents soft-tissue ingrowth into the central portion of the implant where the abutment will ultimately connect. A space screw fits in the center of the implant and does not increase the profile of the implant during the healing phase.

Fig. 31.10 (A,B) An ear template is used to choose the appropriate site for implant placement.

Fig. 31.11 (A,B) A Simplant or Mimics study can be performed to determine quality and quantity of underlying bone.

It is used if implants are placed under an area of existing skin graft or thin skin flap, usually in the orbital region. The surgical incisions are then closed if a two-stage procedure is planned.

If a one-stage procedure is possible, the outer layer of the flap is elevated as an attached split-thickness graft, and underlying soft tissues are removed. The edges around the outside of the flap site are aggressively thinned and the graft is replaced to take on the underlying periosteum. The most common causes of future soft-tissue problems are related to tissue movement around the abutment, and the remaining hair follicles. In non-irradiated tissues, the implants are usually left for approximately 3 months, at which time phase II surgery can occur. In the midface or in patients with a history of radiotherapy, this time period is usually extended to 6–9 months. Usually, two implants are required for auricular reconstruction and at least three implants for orbital reconstruction. Extra implants are often placed as sleepers in the orbital region as the long-term success rates in this region

are not as high as elsewhere. If an implant fails, then a sleeper can be exteriorized, and the patient can continue to wear the prosthesis with minimal interruption.

If a two-stage technique is needed phase II surgery involves exposing the implant, radical thinning of the overlying and surrounding tissue, creation of a hairless, nonmobile zone of 1.0 cm around each abutment, and connection of an abutment to the underlying fixture. Improper soft-tissue surgery is the most common cause of ongoing tissue reaction around the abutment. Other surgical considerations include removal of any residual soft-tissue elements to produce a flat tissue surface for the auricular or nasal prosthesis. More recently there has been success in the mastoid region with one-stage placement of implants under optimal local conditions.^{54,55} Accepted clinical criteria for a one-stage procedure in the mastoid region of older children (>10 years) or adults include:

- no past history of irradiation
- cortical layer of bone greater than 3.0 mm in thickness
- uncomplicated surgery.

The technique is essentially the same as for phase I and II surgery, but both phases are conducted at the same operation. After one-stage surgery, the implant must be protected and not loaded for at least 3 months.

Fig. 31.12 Craniofacial implants and fixtures of commercially pure titanium.

Prosthetic construction

Construction of the prosthesis generally begins 4–6 weeks after phase II surgery or 3–6 months after one-stage surgery when local tissues have healed sufficiently to be a stable base for overlying prosthetic construction. For auricular prostheses a bar superstructure is individually designed and connected to the abutments. Clips on the undersurface of the prosthesis securely attach the prosthesis to the bar and are most commonly used for ears. A magnetic retention system is more commonly used for orbital prostheses and occasionally for auricular prostheses when patient dexterity is limited. The

Fig. 31.13 (A–E) Digital technologies were useful in prosthetic construction in this orbital defect.

Fig. 31.14 Two prostheses are made at the same time with different coloration for different seasons and to prevent a crisis if one prosthesis is lost or damaged. There are clips on the undersurface of the prosthesis for secure attachment to the implant-retained bar superstructure.

prosthesis is first sculpted in wax and related to an acrylic resin substructure containing retentive components. When the prosthesis is anatomically acceptable, a mold is constructed and the prosthesis is made from silicone elastomer.

Digital technologies have been helpful in prosthetic construction.⁴¹ Capture of data from the “normal” side can be done from a moulage or scan of the patient. With computer-aided design software (Mimics, Magics, and Freeform), the model is manipulated and the basic form of the prosthesis is easily constructed using 3D printing (Fig. 31.13). This efficiency optimizes the amount of time needed by the anaplastologist with the patient. Constructing the prosthesis using the anaplastologist’s time and skills efficiently is very important, as they are in limited supply.

Another challenge to the prosthodontist and anaplastologist is color-matching based on the patient’s normal pigments and extrinsic influences such as time of year and patient occupation. One of the newer solutions includes the use of spectrophotometry and computerized color formulation technology for color-matching of the prosthesis to the patient.⁵⁶ Patients will sometimes have summer and winter prostheses to account for subtle pigmentary changes. Many small details and techniques are used to add realism to the prosthesis. Ideally, two prostheses are made at a time (Fig. 31.14). This

BOX 31.5 Ancillary soft-tissue procedures combined with craniofacial osseointegration

Soft-tissue expanders
Scar revision
Free vascularized bone graft
Pedicled bone graft
Alar repositioning
Ectropion repair
Eyebrow reconstruction
Browlift
Static facial sling
Repositioning external auditory meatus
Onlay cartilage graft
Muscle flap
Bone contouring
Rhytidectomy
Tragal reconstruction

prevents a crisis situation if something happens to one of the prostheses. A magnetic retention system is more commonly used for orbital prostheses.

Maintenance program

The long-term success of osseointegration requires an effective ongoing maintenance regimen, analogous to the follow-up in an organ transplantation program. Strong patient commitment is required for success. In particular, conscientious care of the periabutment area is crucial. This includes gentle cleaning on a daily basis, as well as diligent application of appropriately prescribed topical agents (Fig. 31.15) including antibiotic ointment or topical steroid. Our protocol includes a lifetime maintenance recall schedule to impress on them their commitment, which is vital to long-term success. Maintenance visits include assessing the periabutment region, measuring soft-tissue height, checking for tissue reaction, and monitoring the mechanical integrity of the implant–abutment assembly. New prostheses are constructed as needed. The life of an individual prosthesis can vary from 1 to 5 years depending on extrinsic factors such as general care and exposure to sunlight or cigarette smoke.⁶

Ancillary autogenous procedures

It is our belief that treatment of the patient's craniofacial defect is often best managed by a combination of osseointegration and autogenous procedures to optimize the final results (Box 31.5; Figs. 31.16 & 31.17).^{57,58} The goal of the ancillary procedures may include decreasing the size of the facial prosthesis, placing prosthetic margins at junctions of aesthetic units, decreasing the size of the maxillary obturator, improving facial contour, improving symmetry, and bringing viable

Fig. 31.15 Requirements for care at abutment sites.

bone for implant placement into a region compromised by surgery or radiation.

Craniofacial osseointegration outcomes

To evaluate the success of craniofacial osseointegration, several parameters need to be studied.^{59,60} Success from a patient's perspective is the ability to use the prosthesis on a regular basis and its positive effect on quality of life. This contributes to psychological success as much as the aesthetic and functional success. Assessment of outcomes must also include individual implant success rates and local skin response.

Individual implant success rates

Jacobsson *et al.*¹⁸ proposed the following criteria for success of a craniofacial osseointegrated implant:

1. The unattached implant should be immobile when tested clinically.
2. Soft-tissue reactions around skin-penetrating abutments should be type 0 (reaction-free) or type 1 (slight redness) on the Holgers scale,⁶¹ not demanding treatment in more than 95% of observations.
3. Individual implant performance should be characterized by the absence of persistent and/or irreversible signs and symptoms such as pain, infection, neuropathy, and paresthesia.
4. A success rate of 95% in the mastoid process and 90% in the orbital region in nonirradiated bone tissue at the end of a 5-year observation period should be a minimum criterion for success.

Many studies in the literature have documented implant success rates. A 1992 study¹⁸ showed a success rate of 95% in the mastoid and 72% in the orbital region. It was noted that

Fig. 31.16 (A–D) As a child this patient underwent enucleation of the right globe and postoperative radiotherapy for a malignant lesion. He was reconstructed with a combination of autogenous and alloplastic techniques. He had an eyebrow reconstruction, onlay cartilage graft to right zygoma, orbital revision, and an osseointegrated orbital prosthesis.

failures in the mastoid occurred within 6 months of insertion whereas failures in the orbital region tended to occur much later. Further evaluation revealed that the success rate in nonirradiated orbits within this group was 92.1% whereas that of the irradiated group was 62.7%. Subsequently, work by Gransström and others has shown that hyperbaric oxygen therapy both before and after implant placement has significantly improved the success rate of craniofacial osseointegrated implants in irradiated bone. In 1994, Granström and colleagues found that, with hyperbaric oxygen therapy, no implant loss had occurred during a 5-year follow-up period in 48 implants placed in irradiated orbital, nasal, and temporal regions.⁴⁷

Skin response

The most common problems are related to the skin response around the percutaneous abutments. Although this does not usually threaten the long-term success of the individual implant, it requires much of both the clinician's and patient's time to overcome this problem. Occasionally, further surgery may be indicated. Tjellström reported that 15% of his patients accounted for 70% of skin reactions.¹⁷ He reported a grading of no skin reaction in approximately 90% of his patients. A factor contributing to adverse skin reaction was adolescence

because of behavior problems and poor compliance with local hygiene (Fig. 31.18).

Prosthetic success

Several studies have been published documenting prosthetic success from a patient's perspective.^{17,59,62,63} In a study from 1990,¹⁷ only 2 of 94 patients were not wearing their prosthesis at the time of assessment. Tolman and Taylor⁶² evaluated patients with nonimplant-retained prostheses, and only 50% considered their prosthesis stable. After these patients had craniofacial implant prosthetic reconstruction, 93% rated their implant-retained prosthesis as stable. Of 30 patients, 19 wore the prosthesis more than 12 hours per day, three wore the prosthesis 8–12 hours per day, three wore the prosthesis 4–8 hours per day, and five wore the prosthesis less than 4 hours per day. Of 30 patients, 24 viewed the prosthesis as an extension of themselves and part of their body image. Westin *et al.* found 95% of their patients wore their prosthesis every day and in most cases more than 10 hours per day.⁶³ In a recent study by Korus *et al.*⁶⁴ of osseointegrated ear prosthetic patients, 90% of patients rated their confidence as good with their prosthesis compared to 16% without, and 100% felt that the prosthesis felt like part of them. In regard to the implant

Fig. 31.17 (A,B) Medical modeling technology is used to help construct appropriate cartilage graft and to help with implant placement.

Fig. 31.18 Adverse skin reactions can intermittently be a problem requiring treatment. Lower abutment shows no soft-tissue reaction while upper abutment shows some tissue hypertrophy.

system, 55% felt that they had a skin reaction; however, 83% did not consider their reaction severe. Ultimately most patients were satisfied (97% satisfied, and 74% very satisfied). In all, 94% would ultimately undergo the same procedure again and 97% would recommend it to others.

Conclusion

Craniofacial osseointegration has an important role in the treatment of major head and neck defects. It offers treatment options in many situations where in the past only poor ones existed. Patient satisfaction is very high and they often become strong advocates for this treatment modality. Craniofacial

osseointegrated prosthetic reconstruction adds another floor where the reconstructive elevator can stop.

The future of craniofacial osseointegration includes the development of new implants and implant surfaces to stimulate bone formation and remodeling to improve long-term success. Growth factors, stem cells, and new drugs will help improve success rates in compromised tissues. Further developments using advanced digital technologies such as rapid prototyping,^{65,66} image acquisition technology,⁶⁷ software manipulation systems, and color-matching software,⁶⁸ will make prosthetic reconstruction more accurate, faster, and potentially cheaper. New methods of noninvasive testing will allow better evaluation of implants, and better strategies to prevent implant loss will be devised.⁶⁹ Presently skin does not attach to the percutaneous abutment so the connection is maintained essentially as an open wound. Improved understanding of this soft-tissue interface will allow for more use elsewhere in the body, including the extremities, where contamination is more common.⁷⁰ Combining osseointegration technology with microelectronics could produce movable or sensory prosthetics^{71–74} or some type of seeing orbital prosthesis.⁷⁵ Large titanium implants will secure large-extremity prosthetics better.^{76,77} The future is exciting for a whole field of endeavor that started with the chance observation by P.I. Brånemark of an unusual behavior of a metal in a blood flow study in rabbits!

Transplantation in plastic surgery

David W. Mathes, Peter E.M. Butler, and W.P. Andrew Lee

SYNOPSIS

- The most important antigens contributing to allograft rejection are the major histocompatibility complex (MHC) antigens.
- The immune system has two main arms that mediate both rejection and tolerance to foreign antigens: the humoral response (B cells and antibodies) and the cell-mediated response (T cells).
- T lymphocytes have a central role in coordinating the immune response, forming the cell-mediated arm of the immune response.
- Acute rejection takes place days to weeks after transplantation and occurs with rapid onset. This T-cell-mediated response is characterized by fever, graft tenderness, and edema, and loss of function. Interstitial lymphocytic infiltration is seen on microscopic examination.
- Chronic rejection is characterized by fibrosis and severe organ dysfunction. This process usually occurs over years.
- Immunosuppressive medications must inhibit the body's ability to reject a transplanted organ, but not at the expense of the defense network against pathogens.
- Despite the use of powerful immunosuppressive medications most transplant patients experience episodes of acute rejection.
- Two major issues in hand transplantation are the need for maintenance immunosuppression and the evaluation of the functional outcomes of the transplants.
- Clinical hand and face transplantation have expanded over the past 5 years but still are limited by the need for chronic immunosuppression and the threat of rejection.

The fields of transplantation and plastic surgery have always been closely linked. In fact, the age of organ allotransplantation in the US began when Joseph E. Murray, a plastic surgeon, transplanted a kidney between identical twin brothers in 1955.¹ Such "reconstructive surgery" using organ allografts was one of the great achievements in 20th-century medicine. Plastic surgeons often reconstruct tissue defects via transplantation of autologous tissue from other regions of the body. Nonvascularized skin, bone, and cartilage grafts alone or in combination with axial and random flaps are common everyday procedures used to reconstruct tissue defects. However,

these surgical techniques all have significant limitations, often require revisions, and leave the patient with a donor site. Advances in the development of skin substitutes (prepared from allogeneic or xenogeneic sources) and the application of frozen bone allografts have shown the possibility of reconstruction without a donor site but their application is limited. Despite advances in plastic and reconstructive surgery, including the refinement of microvascular techniques and delineation of flap vascular anatomy, many complex wounds, especially those on the central face, still remain outside the realm of possibility for restoring both form and function.

The inability to reconstruct missing tissues accurately occurs when the surgeon must deviate from the principle of replacing "like with like" due to a lack of appropriate autologous donor sources. Thus, the function of a severely injured extremity cannot be adequately restored, the appearance of a severely disfigured face cannot be satisfactorily improved, and both the function and appearance of an amputated extremity cannot be reconstructed. Understandably, the inclination toward tissue transplantation has led plastic surgery researchers to look to non-autogenous sources for reconstructive material.²⁻⁴ However, the ability to engineer tissue from single cell sources has yet to yield a technique that can provide the complex tissue constructs needed. One technique with the potential for providing access to complex vascularized tissue constructs without the need for a donor site is through the process of allotransplantation.

The clinical feasibility of vascularized composite allograft (VCA) has been demonstrated by the successful transplantation of over 107 hands and 37 faces worldwide.⁵⁻¹¹ The field of reconstructive transplantation represents a paradigm shift in the arena of reconstructive surgery. The application of these transplants to patients with complex wounds can provide the reconstructive surgeon with the opportunity to reconstruct with the exact tissues lost. However, unlike traditional solid-organ transplants (kidney, liver, and heart) that consist of relatively homogenous parenchymal tissue, the vascularized composite allograft is comprised of multiple heterogeneous tissue types (skin, bone, and muscle). Each of these distinct

tissue types has been shown to exhibit varying degrees of antigenicity, with skin and mucosa the most antigenic.¹² While solid-organ transplantation is the gold standard for the treatment of end-stage organ failure, there has yet to be true consensus on the use and application of vascularized composite allografts.^{13,14} The survival of the hand and face transplants is dependent on the use of chronic immunosuppression and their application is currently limited to experimental institutionally approved protocols. In order for the field of reconstructive transplantation to expand its indications beyond the experimental arena, techniques need to be designed either to significantly reduce or eliminate the need for chronic immunosuppression. The future direction of this field is heavily dependent on the development of innovative approaches to the use of immunosuppressive agents and tolerance induction protocols.

Nomenclature

A graft is nonvascularized tissue (such as skin) that is harvested from its donor bed and transferred to a recipient site. Its survival relies on ingrowth of new vessels from the recipient bed to restore its blood supply. In contrast, a flap involves the transfer of vascularized tissue (such as muscle and skin) via either the preservation of an axial blood vessel or microvascular anastomoses of that vessel to recipient vessels located adjacent to the wound. An autograft is tissue transplanted from one location to another in the same individual. An isograft is transplanted from a genetically identical donor to the recipient, such as transplants between syngeneic mice and human monozygotic twins. An allograft is transplantation of tissues between unrelated individuals of the same species. A xenograft is transplantation between different species.

Transplantation may also be described in terms of the site into which the tissue is transplanted. Orthotopic refers to transplantation into an anatomically similar site; heterotopic refers to transplantation into an anatomic site different from the site of origin.

Transplantation immunology

Major histocompatibility complex

The most important antigens contributing to allograft rejection are the major histocompatibility complex (MHC) antigens. The MHC proteins are encoded in a gene complex on the short arm of chromosome 6 and have different nomenclature between species: human leukocyte antigen (HLA) in humans, swine leukocyte antigen (SLA) in swine, H-2 in mice, and RT1 in rat. MHC genes are expressed in a codominant fashion, with one haplotype, or set of alleles, inherited from each parent.

There are two major classes of MHC genes. Class I MHC genes encode a transmembrane glycoprotein complex with a polymorphic 44-kDa heavy chain consisting of three extracellular domains (α_1 , α_2 , and α_3). The α_1 domain is highly variable and contains sites for antigen binding. The heavy chain is stabilized by noncovalent binding to a lighter chain, referred to as β_2 -microglobulin. There are three distinct genetic loci for the class I antigens in the human: HLA-A, HLA-B, and HLA-C.

Class I antigens are expressed on nearly all nucleated cells and serve as the primary target for cytotoxic (CD8+) T lymphocytes. Class II MHC genes encode two noncovalently bound transmembrane proteins, a 34-kDa α chain and a 29-kDa β chain. There are three class II loci in humans: HLA-DR, HLA-DP, and HLA-DQ.¹⁵ Class II antigens are expressed primarily on vascular endothelium and cells of hematopoietic stem cell origin such as lymphocytes and macrophages.

Both class I and class II molecules have a specific site at which foreign peptide antigens can be presented after they have been processed by the cell.¹⁶⁻¹⁹ Tissue distribution is not the same in all species: humans, dogs, pigs, and monkeys express class II antigens on endothelial cells, whereas rodents and many species do not.²⁰ Matching of HLA-A, HLA-B, and HLA-DR has been found to be an important factor in determining long-term renal allograft survival.²¹

Other transplant antigens

In addition to the MHC antigens, there are three other classes of surface proteins: ABO blood group proteins, minor histocompatibility antigens, and skin-specific antigens.

The blood group antigens are important in clinical transplantation because they are expressed on vascular endothelial cells. Patients with type A or type B blood develop natural antibodies to the other protein, whereas patients with type O blood develop natural antibodies to both type A and type B proteins. Although ABO antigens will not stimulate cell-mediated rejection, a brisk antibody-mediated attack can rapidly lead to graft failure.²²

Minor histocompatibility antigens are peptides of self origin that are not presented by the MHC complexes. Siblings (other than identical twins) with a completely matched MHC profile will still differ with respect to minor antigens because of allelic variation of the genes encoding those proteins. Although minor antigens will stimulate a cell-mediated response, they will not do so in a primary *in vitro* test. Rejection of a graft due to minor antigens alone, therefore, often proceeds at a slower rate.²³

Skin-specific antigens (Sk antigen) are tissue-specific proteins that can cause graft rejection by a cell-mediated response. Consequently, skin is one of the most difficult tissues to which transplantation tolerance can be induced.²⁴

Immunologic rejection cascade

Cells of immune response

A number of cells with varied but interconnected functions participate in the process of graft rejection. They work together to maintain the two main arms of the immune reaction, the humoral response (B cells and antibodies) and the cell-mediated response (T cells).

Macrophages

The macrophage performs the most ancient cellular defense function: phagocytosis. It is of mesenchymal origin and thought to arise from a bone marrow stem cell. It can freely circulate throughout the body, migrate through lymph nodes, or remain stationary within tissues. Kupffer cells are specialized macrophages that reside in the liver. The Langerhans cell is a specialized macrophage that is specific to the skin. The

macrophage expresses class I antigens on its cell surface, and as a highly specialized immune cell, the macrophage also expresses class II MHC molecules.

Beyond simple destruction of cells, the main purpose of the macrophage is to reprocess the breakdown products of ingested cells. These fragments of foreign protein may then be bundled with a new class II antigen molecule, and during the bundling process, fragments of the foreign protein come to reside in the peptide-binding groove of the class II molecule. When the fragment is exteriorized, it faces outward and is easily recognized by the immune system as foreign. This process is known as antigen presentation. Macrophages also secrete important cytokines,^{25,26} such as interleukin-1 (IL-1). This polypeptide can, in a hormonal fashion, stimulate the immunologic function of responding cells. These cells are critical to the presentation of foreign antigen.

Natural killer cells

Another primitive cell derived from the bone marrow stem cell is the lymphocyte (non-T, non-B) called the natural killer (NK) cell. NK cells are thought to be active in the antitumor response.²⁷ They are able to demonstrate spontaneous tumoricidal properties on exposure to tumor cells. This cell does not require recognition of MHC molecules or antigen processing (as do T cells and B cells).²⁸ However, the exact method this cell uses to recognize foreign cells remains unclear. They are able to kill cells by incorporating a lipophilic protein into the target cell membrane, which leads to increased permeability and cell lysis. NK cells also secrete several cytokines, including interferon- γ , interferon- α , and B-cell growth factor. They may also serve to eliminate cells that fail to express normal self-MHC proteins and thereby be self-reactive. Finally, they appear to serve as a barrier to the engraftment of donor bone marrow after non-MHC-matched bone marrow transplantation.²⁹

Granulocyte

The granulocyte plays an important role in immune homeostasis. Named for their histologic staining properties, the three main cell lines are polymorphonuclear cells, eosinophils, and basophils. All of the cell lines are derived from the same bone marrow precursor. As nucleated cells, they all express class I MHC molecules; however, they do not express class II MHC antigens. In addition, these cells express a number of molecules important for their function (including adhesion and interaction with other immune cells) on their cell surface. These white blood cells carry granules of toxic substances (peroxidases) and substances that attract other white blood cells and cellular elements of the coagulation cascade. When stimulated, the granulocyte secretes these granules, initiating local inflammation in a relatively indiscriminate fashion.

B lymphocyte

Named for their site of origin in the chicken, the bursa of Fabricius, these cells play a central role in immune defense. In humans, the bursa equivalent is thought to be the fetal liver or bone marrow. Once these cells are produced, they migrate to the lymph node and spleen and appear to remain in these organs. These cells express class I and II MHC antigens. They also display a variety of B-cell-specific markers, known as B1–B8 (through which the lines of B cells can be identified).

Finally, they display immunoglobulin on their surface. When stimulated, the B lymphocyte differentiates into plasma cells. These smaller cells serve as factories to produce specific antibodies. These soluble antibodies support the humoral arm of the immune response. Through rearrangement of a highly variable genetic region during immune development, antibodies are produced that can bind countless millions of different epitopes.

Immunoglobulin

Antibodies produced by B lymphocytes and plasma cells take the form of immunoglobulins. Immunoglobulins are proteins of unique structure, composed of heavy and light peptide chains. The “root” of the heavy-chain complex is called the constant fragment. The portion of an immunoglobulin molecule where light chains form complexes with heavy chains, at the site at which the antibody will bind to its target, is designated the antibody-binding fragment (Fab). Myriad possibilities exist for antigen to a specific antibody to be made because the Fab moiety is highly variable in its discrete structure. More than 100 genes code for specific segments of the variable portions of the heavy and light chains, leading to millions of potential immunoglobulin specificities.

There are five general immunoglobulin classes: IgM, IgG, IgE, IgA, and IgD. IgM is the first antibody formed after exposure to common microbial antigens, followed by the more durable IgG. IgE is involved in the hypersensitivity reaction by binding to and activating specialized eosinophils (mast cells). IgA is secreted in saliva, tears, and breast milk and thus augments resistance to infection in these fluids. IgD is found on the surface of immature B lymphocytes; its function remains unclear. Immunoglobulins may be soluble or bound to a cell's surface.

The main function of immunoglobulins is to provide opsonization and to activate complement. Opsonization occurs when the Fab fragment of an immunoglobulin binds to its associated antigen, such as an invading organism. Subsequent macrophage and monocyte phagocytosis of the antibody-coated microorganism is then markedly enhanced. Complement fixation occurs when the antibody–antigen complex triggers the complement cascade.

Complement

An antigen–antibody complex may initiate the complement cascade through a classical pathway. Substances such as endotoxin may, without immunoglobulins, initiate the cascade through the alternative pathway. Both pathways converge with the activation of C3. The sequential activation of proteases, which define the complement cascade, results in a tight cluster of proteins known as the membrane attack complex. This complex is able to rupture the membranes of foreign cells. In the normal host, this cascade is kept in check by the regulatory protein C1 inhibitor.

Dendritic cells

These cells are derived from bone marrow stem cell progenitors and are highly specialized antigen-presenting cells. They appear to have little to no effector function. They reside in the intracellular and interstitial space but migrate through the lymphatics and to the spleen when activated. There they present their antigens to T-cell-rich areas.

T lymphocytes

T lymphocytes have a central role in coordinating the immune response, forming the cell-mediated arm of the immune response. The T lymphocyte is named for its site of origin, the thymus, and is one of the central elements of the immune system. T cells derive from fetal stem cells in the thymus and undergo an extensive process of education and deletion before being released into the body. The maturing T cells are selected to recognize self MHC antigens and become tolerant to them. Those cells that demonstrate too high an affinity to self are eliminated by clonal deletion. Failure of this process appears to lead to autoimmunity.

These cells express both class I and class II antigens. In addition to HLA surface markers, lymphocytes also possess cell surface markers that serve to distinguish one subpopulation from another within the same individual. These are all glycoproteins and are described by the common determinant (CD) nomenclature (e.g., CD3).

Three broad classes of T cells are helper T (T_H) cells, cytotoxic T cells, and suppressor T cells. All T cells express CD3 on the cell surface. Cytotoxic T cells (cells that effect target cell killing) express CD8. Suppressor T cells that can buffer and down-regulate the immune response also express CD8.^{30,31} T_H cell, however, expresses CD4 and serves to amplify the immune response through its interaction with other cells and secretion of critical cytokines. Each T cell expresses a T-cell receptor (TCR) capable of binding antigen. The TCR, a 90-kDa heterodimer composed of an α chain encoded on chromosome 14 and a β chain encoded on chromosome 7, is located close to the CD3 antigen and the CD28 antigen. The TCR is relatively flat and possesses an outward-facing surface. This "antigen recognition platform" is the critical interface for foreign peptide in the binding groove. As with B-cell development, T cells undergo rearrangement of genes coding for a hypervariable region on the receptor proteins. This allows a body's population of T cells to respond to a nearly limitless array of foreign antigens, with each individual T cell capable of binding one specific antigen.

T-cell binding and activation

Although the TCR is capable of binding antigen, it will not recognize the target molecule by itself.³² The TCR can bind antigen only if it has been processed and presented by an antigen-presenting cell together with an MHC molecule; thus, it recognizes the MHC together with the target antigen. This limitation of binding is referred to as MHC restriction. CD4 (helper) T cells can only bind antigen presented with MHC class II molecules; CD8 (cytotoxic) T cells recognize antigen along with MHC class I proteins. The T_H cell is most critical to the immune response because its activation results in the production of cytokines that are necessary for the function of many other immune cells. Binding of a CD4 cell to an antigen-presenting cell that expresses target antigen together with MHC class II molecules initiates a predictable cycle of intercellular communication. The antigen-presenting cell is stimulated to produce the cytokine IL-1, a powerful chemoattractant, a primary mediator in the acute-phase reaction, and a potent activator of lymphoid cells. The T cell, in turn, secretes IL-2, which is a required stimulant for differentiation and proliferation of T cells. The IL-2 produced by the bound T cell has autocrine function by binding to newly expressed self IL-2

receptors. Secreted IL-2 also has paracrine function that affects other T cells in the region, such as CD8 cells, which require IL-2 for activation but do not produce it themselves. As CD4 cells become further activated, they secrete IL-4 and IL-5, which stimulate the maturation and proliferation of B lymphocytes. Furthermore, there is evidence that two subsets of CD4 cells, T_H1 and T_H2 , function to enhance alloreactivity and stimulate antibody production by B cells, respectively. With such a central role by CD4 cells in cell signaling, it is easy to understand the severely compromised immune response from the loss of host CD4 cell function secondary to human immunodeficiency virus infection.³³⁻³⁶

Antigen recognition and graft rejection

In the case of allograft tissue, foreign antigens would be recognized by host T cells after being processed by host antigen-presenting cells and presented in the context of self MHC. This is termed indirect presentation. In addition, host T cells can directly recognize donor MHC on donor antigen-presenting cells, termed direct presentation. This mechanism helps explain the more vigorous response to allograft tissue than to foreign peptides alone.³⁷

Clinically, rejection of allograft tissue can proceed at different levels of intensity for different tissues. The common component for rejection of any graft is inflammation. This may be manifested as a loss of graft function with local or systemic signs of inflammation. Several distinct clinical syndromes of graft rejection with different time courses have been noted. These syndromes differ with regard to the underlying primary immunologic process.

Hyperacute rejection occurs almost immediately after perfusion of the allograft with host blood. It is the result of preformed antibodies to either ABO blood group proteins or donor MHC molecules enacting a rapid attack on the donor tissue. Complement activation results in destruction of vascular endothelial cells and induces rapid thrombosis of vessels as well as an amplification of the inflammatory signal. Standard screening before transplantation should detect preformed antibodies, making hyperacute rejection a rare clinical entity. Many mammals possess preformed antibodies to other species that stand as a major obstacle to xenotransplantation.³⁸

Acute rejection takes place days to weeks after transplantation and occurs with rapid onset. This T-cell-mediated response is characterized by fever, graft tenderness, and edema, and loss of function. Interstitial lymphocytic infiltration is seen on microscopic examination. In addition, severe forms of acute rejection may include a humoral attack on the graft, resulting in a vasculitis.³⁹

Chronic rejection is an indolent process occurring months to years after transplantation. It is characterized by a progressive loss of tissue architecture with fibrosis and mononuclear cell infiltration. The etiology of chronic rejection is not well understood and may be multifactorial. The process may be slowed because of immunosuppression. It also may result from the cumulative effect of damage to the graft from ischemia during transplantation, graft infection, or drug toxicity.

Inflammatory mediators in transplantation

In addition to the direct cellular interaction observed during an immune response there are also multiple inflammatory mediators involved in immune activation and regulation.

These include cell adhesion molecules (CAM), cytokines, and chemokines that are all critical to a functioning immune system. Cytokines are transient regulatory proteins that a wide variety of cells can produce in response to stimulation. These proteins can act locally by binding to a cell from the same cell line (autocrine) or to the target cell in the vicinity (paracrine).⁴⁰ The cytokines are divided into proinflammatory cytokines (IL-1 α , IL-1 β , IL-6; tumor necrosis factors: TNF- α , TNF- β), cytokines involved in T-cell differentiation (IL-2, IL-4, IL-5, IL-10, IL-12, IL-13, and interferon- γ), and cytokines of immunoregulatory function belonging to the transforming growth factor- β family, which primarily promotes wound healing and fibrosis.⁴⁰

Chemokines are a subset of cytokines that are currently defined as small chemotactic cytokines. Chemokines, which are constitutively expressed, are involved in homeostatic lymphocyte trafficking to the lymphoid organs and bind to the cellular component by a specific chemokine receptor. The main role of proinflammatory chemokines (macrophage inflammatory protein-1 α (MIP-1 α), MIP-1 β , monocyte chemoattractant protein-1 (MCP-1), and RANTES) is to attract neutrophils to an inflammatory site and trigger T lymphocytes to elicit an additional inflammatory response.⁴¹ In humans, CCR1-positive cells increase in the peripheral blood of renal allograft recipients before acute rejection.⁴² In addition, CCR1 mRNA was found to be expressed in cells derived from biopsies from renal allografts.⁴³ Ruster *et al.* described an increased number of CCR1-positive cells in glomeruli during rejection.⁴⁴ Mayer *et al.* reported that the mRNA expression of CCR1 was associated with the decrease of renal function in allografts with an acute rejection episode.⁴⁵ Thus, it is clear that chemokines play an important role in allograft rejection and interruption of these interactions could have an impact on allograft survival.

CAMs play a role in leukocyte migration from the circulation to tissues. Three types of CAM are involved in the transmigration process: selectins (L-, E-, and P-selectins) mediating the rolling of leukocytes along the vascular endothelium, integrins (intercellular adhesion molecule-1 (ICAM-1), vascular CAM-1 (VCAM-1), mucosal addressin cellular adhesion molecule-1 (MAd CAM-1)) leading to leukocyte adhesion to the endothelium, and finally immunoglobulin superfamily platelet endothelial CAM-1 (PECAM-1), responsible for transmigration of leukocytes.⁴⁶ The complex specific migration of leukocytes to the target tissue requires a coordinated process of proinflammatory mediators. Proinflammatory cytokines, IL-1 α and TNF- α , may induce expression of proinflammatory chemokines. Chemokines play a major role in the activation of integrins needed for adhesion of rolling leukocytes to the vessel endothelium, and this process leads to leukocyte transmigration to the surrounding tissue, initiating the inflammatory process.

Immunologic screening

Methods are available to predict the compatibility of donor tissue to a particular recipient. The greatest value of these clinical tests is to exclude recipients who would be expected to manifest a hyperacute rejection to a specific donor organ.

Blood group typing is an important first step in determining transplant compatibility. An ABO mismatch will result in certain failure because of preformed antibodies.⁴⁷ Although it

is possible to transplant type O donor tissue into type A or type B recipients, the limited supply of donor organs in the US makes this practice uncommon.

HLA typing is used to match organs with potential recipients. Serologic methods are employed to type HLA-A, HLA-B, and HLA-DR. A heterozygous individual with a complete match at all these loci is referred to as a six-antigen match. For renal allografts, HLA matching has been shown to affect graft survival. Kidneys transplanted from HLA-identical siblings have a 3-year success rate that well exceeds 90%, whereas parent-to-child grafts have an 82% survival. Cadaveric kidney grafts have a 70% 3-year survival rate.⁴⁸ MHC class II matching has been found to be more important than class I matching for renal transplantation; the reverse appears to be true for liver transplantation. This would suggest differences in mechanisms of graft rejection for different tissues.⁴⁹ Serologic tissue typing has certain limitations. An HLA antigen can be identified only if it is being searched for with a specific antibody. For example, if only a single HLA-DR phenotype is identified in donor tissue, the individual could be either homozygous for that allele or heterozygous with an unrecognized HLA-DR antigen. This method of testing fails to type the other class II antigens, HLA-DP and HLA-DQ.

Crossmatching is a test that detects the presence of preformed donor-specific antibodies in the serum of a particular recipient. It represents the final definitive screening measure before transplantation. In this lymphocytotoxicity assay, donor lymphocytes are incubated with recipient serum and complement. Cell viability is then assessed by a dye exclusion technique. A positive crossmatch, indicated by lysis of the donor lymphocytes, suggests that a hyperacute reaction is likely to occur. One pitfall of this test, however, is that organ-specific antibodies may be missed if those antigens are not expressed on the lymphocytes being evaluated.

Antibody screening is another modality used in clinical transplantation. Serum from prospective transplant recipients is routinely tested in a lymphocytotoxicity assay against a panel of cells from different donors with known HLA antigens. The percentage of panel cells lysed reflects the degree of panel-reactive antibody (PRA), demonstrating HLA antibodies in an individual's serum. A high PRA suggests that a patient is unlikely to have a negative crossmatch. This information is used in determining organ allocation when the tissue must be transplanted quickly. Individuals are likely to have a high PRA if they have been sensitized by previous transplantation, pregnancy, or blood transfusions.

Current immunosuppression for VCA

The multiple pathways and mechanisms employed by the immune system to defend the body against both extracellular and intracellular pathogens have presented a significant barrier to the survival of transplanted allografts. Immunosuppressive medications must inhibit the body's ability to reject a transplanted organ, but not at the expense of the defense network against pathogens. The use of several immunosuppressive agents has allowed the inhibition of the immune system that maximizes the protection of the allograft with the least cost to the body's overall ability to fight infection and tumors (Table 32.1).

Table 32.1 Antibody-mediated drugs

Agent	Mechanism	Action	Side-effects
Antilymphocyte			
Antilymphocyte globulin	Antibodies directed against antigens on lymphocytes	Promotes T-cell clearance through complement-mediated lysis	Thrombocytopenia, leukopenia, increased risk of viral reactivation, serum reaction
Antithymocyte globulin	Antibodies directed against antigens on thymocytes	Promotes T-cell clearance through complement-mediated lysis	Thrombocytopenia, leukopenia, increased risk of viral reactivation, serum reaction
Alemtuzumab	Antibody against CD52	Eliminates T cells by antibody-dependent cellular cytotoxicity	Thrombocytopenia, leukopenia, increased risk of viral reactivation, serum reaction
OKT3	Murine monoclonal antibody directed against the CD3 subunit on human T cells	Eliminates T cells by the reticuloendothelial system; blocks cytotoxic activity of activated T cells	Significant cytokine syndrome, reactivation of viruses, post-transplantation lymphoproliferative disease
Anti-IL-2			
Daclizumab, basiliximab	Blocks binding to CD25 (high-affinity chain of IL-2 receptor)	Limits T-cell expansion; acts only on activated cells	None
CTLA-4 Ig			
Belatacept	Selective T-cell costimulation blocker binds to CD80 and CD86 receptors on antigen-presenting cells (APC)	Blocks the required CD28-mediated interaction between APCs and T cells needed to activate T lymphocytes.	Post-transplant lymphoproliferative disorder, other malignancies, and serious infections. Increased risk for developing post-transplant lymphoproliferative disorder, predominantly involving the CNS. Recipients without immunity to Epstein–Barr virus are at a particularly increased risk
IL-2, interleukin-2.			

In all of the transplanted organs including hand and face transplants, it appears that it is central to prevent allograft recognition during the peritransplantation period. This is currently achieved through so-called induction protocols. Several agents are currently used to protect the transplant during that period of cytokine excess observed after surgery (Table 32.2). After the induction agents are used, “maintenance” medications are used to maintain the transplant. Finally, when ongoing rejection occurs, it is often necessary to use “rescue” agents to stop ongoing rejection and salvage a transplant that would otherwise be lost.

Corticosteroids

These agents remain a central tool for both the prevention and treatment of allograft rejection. Whereas steroids are not effective as solitary agents to prevent rejection, they have been shown to improve graft survival in combination with other agents. When used at high doses, they can also treat ongoing acute cellular rejection. Despite these uses, steroids also contribute to the morbidity associated with modern immunosuppression.

Glucocorticosteroids bind to an intracellular receptor after nonspecific uptake in the cytoplasm. The receptor–ligand complex then enters the nucleus, where it acts as a DNA-binding protein and increases the transcription of several genes.⁵⁰ The most important gene is thought to be *IκBα*, which binds to and prevents the function of NF-κB (a key proinflammatory cytokine that is an important transcription factor for

T-cell activation). Steroids block the production of IL-1 and TNF-α by antigen-presenting cells. They also block interferon-γ production by T cells and migration and lysosomal enzyme release by neutrophils. Steroids also mute the up-regulation of the MHC and, through their diminution of the inflammatory responses, decrease the degree of costimulation in the environment. Steroids do not have an impact on the production of antibody.

Antiproliferative agents

Azathioprine

This was the first immunosuppressive agent employed in transplantation and is now largely a historical transplant medication. Azathioprine undergoes conversion in the liver to 6-mercaptopurine and then to 6-thioinosine monophosphate. These derivatives inhibit DNA synthesis by alkylating DNA precursors and inducing chromosome breaks through interference with DNA repair mechanisms. In addition, they inhibit the conversion of inosine monophosphate (IMP) to adenosine monophosphate and guanosine monophosphate (GMP), which depletes the cell of adenosine. The effects of azathioprine are nonspecific, and it acts not only on dividing T cells but on all rapidly dividing cells. The primary toxic effect is on the bone marrow, gut, and liver cells. Azathioprine is ineffective as a single agent and cannot be used as a rescue agent. It has been used for maintenance when it is given in combination with steroids and a calcineurin inhibitor.

Table 32.2 Immunosuppressive drugs

Agent	Mechanism	Action	Side-effects
Calcineurin inhibitors			
Cyclosporine	Binds to cyclophilin, blocks the NF-AT transcription factor, inhibits production of IL-2, and promotes production of TGF- β	Prevents cytokine transcription and arrests T-cell activation	Nephrotoxicity, hypertension, neurotoxicity
Tacrolimus (FK506)	Binds to FK-binding protein, blocks the NF-AT transcription factor, inhibits production of IL-2, and promotes production of TGF- β	Prevents cytokine transcription and arrests T-cell activation	Nephrotoxicity, neurotoxicity, diabetogenicity
Antiproliferative agents			
Azathioprine (Imuran)	Inhibits DNA synthesis, interferes with DNA repair mechanisms, and inhibits conversion of IMP to AMP and GMP	Blocks the proliferative response (T and B cells)	Bone marrow suppression, hepatotoxicity
Mycophenolate mofetil	Noncompetitive, reversible inhibitor of IMP dehydrogenase; interrupts production of GTP and dGTP; prevents critical step in RNA and DNA synthesis	Blocks the proliferative response (T and B cells), inhibits antibody formation, and prevents clonal expansion of cytotoxic T cells	Gastrointestinal toxicity, bone marrow suppression
Corticosteroids			
Corticosteroids	Binds to intracellular receptor, increases transcription of gene for I κ B α , and prevents the transcription of NF- κ B (a key activator of proinflammatory cytokines)	Blocks IL-1 and TNF- α production by antigen-presenting cells, blocks up-regulation of the MHC, inhibits production of interferon- γ by T cells and lysosomal enzymes and migration by polymorphonuclear cells	Osteonecrosis, osteoporosis, growth suppression, glucose intolerance, hypertension, central nervous system effects
Macrolide inhibitors			
Sirolimus (rapamycin)	Binds to FK-binding protein, impairs signal transduction by the IL-2 receptor, and arrests the cell cycle of lymphocytes	Interrupts T-cell activation pathway	Hypertriglyceridemia, bone marrow suppression
AMP, adenosine monophosphate; dGTP, deoxyguanosine triphosphate; GMP, guanosine monophosphate; GTP, guanosine triphosphate; IL-2, interleukin-2; IMP, inosine monophosphate; TNF- α , tumor necrosis factor- α ; MHC, major histocompatibility complex; TGF- β , transforming growth factor- β ;			

Mycophenolate mofetil

Mycophenolate mofetil (MMF), which was approved for use after allograft transplantation in 1995, acts through noncompetitive, reversible inhibition of IMP dehydrogenase.⁵¹ This modification improves the bioavailability of mycophenolic acid. Physiologic purine metabolism requires that GMP be synthesized for the subsequent production of guanosine triphosphate (GTP) and deoxyguanosine triphosphate (dGTP). GTP is required for RNA synthesis and dGTP for DNA synthesis. GMP is formed from IMP by IMP dehydrogenase. MMF prevents a critical step in both RNA and DNA synthesis. However, MMF does not affect the “salvage pathway” for GMP production that is present in most cells. This pathway is not present in lymphocytes, and MMF exploits this difference and spares most other cells in the body, including neutrophils. MMF blocks the proliferative response in both T and B cells, inhibits antibody formation, and prevents clonal expansion of cytotoxic T cells.

MMF decreases biopsy-proven rejection and the need for antilymphocyte agents in rescue therapy compared with azathioprine.^{52–54} MMF has replaced azathioprine in clinical transplantation. However, MMF cannot be used as a sole immunosuppressive agent and must be paired with either

steroids or, more commonly, calcineurin inhibitors (tacrolimus and cyclosporine).

Calcineurin inhibitors

Cyclosporine

Cyclosporine is a cyclic endecapeptide that was isolated from the fungus *Tolypocladium inflatum gams* in 1972.^{55,56} This drug acts as a T-cell-specific immunosuppressant, and its mechanism of action is primarily through its ability to bind to the cytoplasmic protein cyclophilin.⁵⁵ The cyclosporine–cyclophilin complex forms a high-affinity bond with calcineurin–calmodulin complex and blocks the calcium-dependent phosphorylation and activation of NF-AT. The interference with NF-AT prevents the subsequent transcription of the gene encoding IL-2. This process also interrupts other genes critical for T-cell activation. In addition, cyclosporine increases transforming growth factor- β transcription, which appears to down-regulate T-cell activation further, decrease blood flow to the area, and activate pathways critical to wound healing.^{56,57}

The effect of cyclosporine is reversible because it blocks TCR signal transduction but does not inhibit costimulatory signals.³⁸ If the drug is withdrawn, the T cell is not anergic but is again capable of mounting an attack on its target. The effects of cyclosporine can be overcome with the exogenous administration of IL-2. This may explain why cyclosporine is not effective once rejection is ongoing; it is only useful as a maintenance agent and is ineffective as a rescue agent.

Cyclosporine also has significant toxicity associated with its administration. It has significant vasoconstrictor effect (mediated by transforming growth factor- β) on the proximal renal arterioles and this decreases renal blood flow by 30%. Its effects on the kidney can promote fibrosis and hyperkalemia and may interfere with the resolution of acute tubular necrosis. The drug also has neurologic side effects, such as tremors, paresthesias, headache, depression, confusion, and seizures. It may also cause hypertrichosis and gingival hyperplasia. The use of cyclosporine in solid-organ transplantation protocols has largely been replaced by tacrolimus.

Tacrolimus

Tacrolimus (FK506), a macrolide produced by *Streptomyces tsukubaensis*, was discovered in 1986. Tacrolimus, like cyclosporine, blocks the effects of NF-AT, prevents cytokine transcription, and arrests T-cell activation. The intracellular target is an immunophilin protein distinct from cyclophilin known as FK-binding protein.^{58,59} The effect is additive to that of cyclosporine, and these drugs cannot be given together because of the prohibitive toxicity. Tacrolimus also increases the transcription of transforming growth factor- β and thus shares both the beneficial and toxic effects seen in the administration of cyclosporine. It is, however, 100 times more potent in its inhibition of the production of IL-2 and interferon- γ . The renal side effects are similar to those with cyclosporine. It has more pronounced neurologic side effects and a diabetogenic effect. The cosmetic side-effects are less than those with cyclosporine. This drug has been proved to be effective as a maintenance drug for both liver and kidney transplantation. It has only minimal use as a rescue agent.⁶⁰

A topical preparation of tacrolimus has recently been developed and approved for use in atopic dermatitis. Its mechanism of action and local route of administration render it an attractive therapeutic alternative for the treatment of various autoimmune dermatologic conditions and could be of potential use in CTA. It has also been widely used in clinical hand and face transplant immunosuppressive protocols for both maintenance and treatment of rejection.⁵ There has also been some evidence that it can be used in graft-versus-host disease (GvHD).⁶¹ The mechanism by which topical tacrolimus may be effective in GvHD is the suppression of local cytokine secretion such as IL-2, interferon-gamma, and TNF- α in the skin.⁶² The only adverse events reported in its dermatologic applications have been local irritation, pruritus, erythema, and burning.^{63,64} The majority of these symptoms are reported to occur when initiating treatment and systemic effects have not been observed.

Rapamycin

Rapamycin is a macrolide antibiotic derived from *Streptomyces hygroscopicus* and is structurally similar to tacrolimus.^{65,66} However, they antagonize each other's biologic activity. Both

of the drugs bind to the same FK-binding protein, but rapamycin does not affect the calcineurin activity.^{67,68} Instead, the interaction of rapamycin and FK-binding protein complex impairs signal transduction by the IL-2 receptor through its interaction with a cytoplasmic protein (RAFT-1). In doing so, the p70 S6 kinase cascade is interrupted and T cells are prevented from entering into the S phase of cell division.⁶⁹ Thus, rapamycin is able to interrupt T-cell activation and proliferation, even in the presence of IL-2.⁷⁰ Other receptors that are affected are IL-4, IL-6, and platelet-derived growth factor.

Rapamycin has been shown to prolong allograft survival in multiple animal models and is being used in several drug clinical regimens.⁷¹ The drug is most commonly used after the peritransplant period to replace tacrolimus.⁷² It has also been applied to the experimental human hand transplantation patients who have experienced renal toxicity secondary to tacrolimus.⁷³ This drug has little to no nephrotoxicity. It does, however, demonstrate some bone marrow toxicity and has been observed to cause hypertriglyceridemia. Finally, it appears to interrupt the process of wound healing and caution should be applied before using it immediately after surgery.

Antilymphocyte preparations

Antilymphocyte/antithymocyte globulin

Antilymphocyte globulin (ATG) is produced by inoculation of heterologous species with human lymphocytes, collection of the plasma, and then purification of the IgG fraction. The result is a polyclonal antibody preparation that contains antibodies against many of the antigens on human lymphocytes. When thymocytes are used as the inoculum instead of lymphocytes, the product is known as ATG. The most common ones employed in transplantation are made in the horse (ATGAM, Pharmacia & Upjohn, Kalamazoo, MI) and in the rabbit (ATG (Thymoglobulin), SangStat Medical, Fremont, CA).

The mechanism behind the effectiveness of these drugs is through the coating of the T cells by the antibodies.^{74,75} These coated T cells are then eliminated by complement-mediated lysis and opsonin-induced phagocytosis. The mere presence of the antibodies on the surface of the T cell reduces its ability to express an effective TCR signal. The overall impact of the antibodies is functionally to remove the primary effector cells required for acute rejection after transplantation.

These drugs have been employed as induction agents at the time of transplantation to reduce the possibility that T-cell-mediated antigen recognition will occur when the graft is in its most vulnerable state. These drugs are also used as rescue agents, and their effectiveness is based solely on their ability to destroy cytotoxic T cells. Most of the side effects are due to the drug's heterologous origin and the fact that it can also bind to other cells. Therefore, one can observe thrombocytopenia, anemia, and leukopenia. The most common reaction is a cytokine release syndrome. Chills and fevers occur in up to 20% of patients. A rash consisting of raised erythematous wheals on the trunk and neck is seen in 15% of patients. The use of antilymphocyte drugs has been associated with the reactivation of viral disease.

The extent of peripheral lymphocyte depletion in the blood appears to be dose-dependent. Although these agents

preferentially bind to T cells, they may also bind to B cells, dendritic cells, and other nonlymphoid cell lines, especially at high doses. In fact, two pilot studies have demonstrated that high-dose ATG induction can facilitate monotherapy maintenance immunosuppression in selected patients, with graft and patient survival comparable to the current standard.^{76,77} Treatment with ATG has been shown to be associated with both short- and long-term changes in T-cell populations, generating altered homeostasis characterized by expansion of specific T-cell subsets that have been shown to exhibit regulatory suppressor functions. The use of ATG induction has been demonstrated to result in a lower incidence of acute rejection and improved graft survival during the first year after transplantation. However, as has been observed with most induction agents, patient and graft survival after 20-year follow-up were not affected.⁷⁸

OKT3

This is a murine monoclonal antibody that is directed against the signal transduction subunit on human T cells (CD3). OKT3 is thought to bind to the CD3 subunit found on all mature T cells and results in the internalization of the receptor, thus preventing antigen recognition and TCR signal transduction.^{79,80} In addition, T-cell opsonization and clearance by the reticuloendothelial system occur. After the administration of OKT3, there is a rapid decrease in the circulating CD3+ T cells. There is little or no effect on those cells in the spleen and lymph nodes or thymus. After several days, there is a return to T cells that are CD4+ and CD8+ but that do not express CD3. These “blind” T cells remain incapable of binding to antigen and interfere with the process of antigen recognition and generation of cytotoxic T cells. Finally, OKT3 blocks the cytotoxic activity of already activated T cells by an inappropriate degranulation when the CD3 is bound by OKT3. This mechanism is central to its effectiveness but also to one of its most significant side effects.

The administration of OKT3 can lead to a profound systemic cytokine response that can result in hypotension, pulmonary edema, and a fatal cardiac myodepression. In about 2% of patients, this syndrome is manifested as an aseptic meningeal inflammation. Methylprednisolone must be administered before the delivery of OKT3 to blunt this adverse reaction. This syndrome abates with subsequent doses. OKT3 has been used as a rescue agent to treat acute renal allograft rejection. OKT3 has also been employed as an induction agent. The drug is superior to steroids in halting ongoing rejection. However, it has also been shown to cause a high viral reactivation rate for cytomegalovirus, Epstein-Barr virus, and other viruses. It has been associated with high rates of post-transplantation lymphoproliferative disease. Due to its association with these significant complications, its use is extremely limited now. This is especially true after the release of newer induction agents such as alemtuzumab and maintenance drugs such as rapamycin.

Anti-IL-2

Two monoclonal antibodies have become available for use in renal transplantation and have also been employed in some hand transplantations. Both of these agents (daclizumab and basiliximab) are directed against CD25, the high-affinity chain

of IL-2 receptor.^{81,82} These agents were designed to have the same indications for treatment as ATG and OKT3, without the significant side effects of those agents.

The high-affinity chain on the IL-2 receptor is required for T-cell expansion and targeting. This receptor offers the advantage that the CD25 receptor is present only on those active T cells. Theoretically, this agent should affect only those cells that have been activated against a new allograft. This agent is also useful in that it does not lead to the activation of the T cell and therefore potential cytokine release, as is seen with OKT3. These agents have also had several of the murine portions of the molecule replaced with human IgG, thus eliminating much of the nonspecific reactions observed in the heterogeneous antibodies. These agents can be used in the induction phase, but because IL-2 is needed only in the initial activation of T cells, it does not appear to be useful to stop ongoing rejection. Early studies of use as induction agents demonstrated a lower incidence of acute rejection but no long-term graft prolongation in both cardiac and renal allografts.⁸³

Currently it is used as induction therapy with two doses (day 0 and day 4) as part of double- or triple-immunotherapy regimens in adult renal transplant recipients and appears to reduce acute rejection episodes without increasing the incidence of biopsy-proven acute rejection than alemtuzumab induction. Basiliximab is generally associated with a tolerability profile that is similar to that reported with placebo, and better than that reported with ATG.⁸⁴ The drug does appear to allow for reduced dosage of corticosteroids or calcineurin inhibitors, while maintaining adequate immunosuppression, thereby reducing the potential for adverse effects associated with these co-administered agents. However, its use as an induction agent is usually limited to those patients who cannot tolerate either alemtuzumab or ATG.

Alemtuzumab

Alemtuzumab is an anti-CD52 antibody that has enjoyed increased use in solid-organ transplantation as a lympho-depleting induction agent. CD52 is expressed on most T and B lymphocytes, NK cells, and monocytes. Alemtuzumab profoundly depletes T cells from peripheral blood for several months with a somewhat reduced effect on B cells, NK cells, and monocytes (in descending order).⁸⁵⁻⁸⁹ It has very minimal effect on CD34+ hematopoietic stem cells. The initial enthusiasm for its application in solid-organ transplantation was based on research by Calne *et al.*, where 33 kidney recipients were treated with alemtuzumab in combination with low-dose cyclosporine. These patients were then compared to the unit's historical control of patients on standard triple therapy.^{90,91} The 5-year survival of these two groups was similar and this finding led to the initial suggestion that the use of this agent could lead to “prope” tolerance (graft acceptance with reduced immunosuppression).⁹¹ However, later attempts to use the drug alone or in combination with deoxyspergualin led to 100% acute rejection, demonstrating that the drug itself was not tolerogenic. This may be due to the lack of CD52 expression on plasma cells and poor effect on memory T cells. Alemtuzumab combined with a single agent for maintenance (low-dose calcineurin inhibitors) demonstrated safety and efficacy, but has an unacceptably high rate (28%) of early cellular and humoral acute rejection. The drug is currently used as an induction agent with tacrolimus and MMF. Several

groups have used it as their induction agent of choice in clinical hand transplants. However, its use is limited due to a lack of availability and limited production.

Belatacept (CTLA-4 Ig)

Belatacept, a fusion protein between a modified extracellular domain of CD152 and human IgG1, is approved for use as a replacement for tacrolimus in kidney transplantation. Belatacept is a selective costimulation blocker and is clinically indicated as a CNI inhibitor substitute with mycophenolate mofetil and steroids after renal transplantation. Studies in murine models have shown synergy between costimulation blockade and mTOR inhibitors such as rapamycin. Studies in nonhuman primates have demonstrated that the combination of belatacept and sirolimus prolongs renal and islet allograft survival. Clinically, phase III trials have shown supremacy of belatacept in the conservation of renal function and other adverse events compared to CNIs. Its clinical use in VCA transplantation has been limited. There have been reports of transitioning patients from tacrolimus to belatacept to preserve renal function. Cendales reported a case of a hand transplant recipient who developed recurrent acute rejection with alloantibody formation and concomitant calcineurin inhibitor nephrotoxicity that appeared to resolve upon conversion from a maintenance regimen of tacrolimus, mycophenolate mofetil and steroids to belatacept and sirolimus.⁹² There have also been reports from the Austrian group that in three out of four patients the addition of belatacept allowed them to lower the dose of tacrolimus in their drug regimen.

Immunologic tolerance

The ultimate goal of transplantation science is to make genetically disparate organs or tissues be accepted and regarded as self. This would make chronic immunosuppression obsolete and allow the recipient to maintain an intact immune system to protect against infections and malignant neoplasms. As true immunologic tolerance would be “functionally complete”, the life expectancy of the organ would not be limited by chronic rejection. This section provides an overview of the various mechanisms of T- and B-cell tolerance and what is known about their role in models of transplant tolerance.

In the transplantation setting, it appears that T-cell-dependent immune responses are regarded as the primary cause of graft rejection. Thus, T-cell tolerance is important to the generation of tolerance to organ allografts. Mechanisms of T- and B-cell tolerance can be divided into three broad categories: clonal deletion, anergy, and suppression. Clonal deletion is the process whereby T cells with particular antigen specificity are eliminated from the repertoire. Anergy is a state in which T cells can recognize a foreign antigen but are functionally inactive and do not generate an immune response. Suppression implies the presence of cells that are capable of actively preventing other T cells from generating a response. The current thought on the mechanism of suppression is based, in part, on direct action of T-regulatory cells (T regs). These mechanisms are not mutually exclusive, and the establishment of tolerance may depend on more than one of these pathways. The application of these

mechanisms for the induction of tolerance could offer the future plastic and reconstructive surgeon the transplantation of foreign tissues without the need for prolonged immunosuppression.

Clonal deletion

Clonal deletion is the process in which T cells that express a TCR specific for a certain antigen are eliminated. The deletion of these cells can occur in the thymus (central deletion) or extrathymically in the peripheral tissues (peripheral deletion). The thymus is the major site for the generation of immunocompetent T lymphocytes. T-cell progenitors migrate from the bone marrow to the thymus, where they undergo a well-defined pathway of maturation. Once the T cells express their respective TCRs, they then undergo a process of selection. During this process, cells with low-affinity TCRs are not stimulated to progress; this is called positive selection. T cells in the thymus with a high affinity for self antigen are eliminated by a process called negative selection. When this process is complete, the remaining T cells should be able to recognize self and mount a response only when they encounter foreign antigen. Extrathymic clonal deletion has been described in several experimental models using exogenous antigens⁹³⁻⁹⁵ as well as self antigens,⁹⁶⁻⁹⁸ demonstrating that elimination of self-reactive antigens can occur after maturation in the thymus. This mechanism may ensure tolerance to self antigens not expressed in the thymus. Several strategies attempt to influence this process.

The acceptance or tolerance of one's own tissues first develops *in utero* along with an immunologic ability to recognize foreign tissue. This phenomenon was successfully exploited by Medawar⁹⁹ in his original experiments in which strain-specific neonatal rodents were injected with donor cells and went on to accept skin allografts. The production of the tolerant state in an adult can be achieved experimentally by various methods. A combination of total body irradiation to remove mature recipient T cells followed by donor bone marrow infusion before transplantation induces a state of chimerism. (The term *chimera* is derived from the Greek mythological figure composed of parts from different animals.) The chimeric host then develops an immune system that is tolerant of both donor and self antigens. A further refinement is the use of total lymphoid irradiation; the marrow cavities of long bones are protected during irradiation, thus producing a state of mixed chimerism.¹⁰⁰ These animals have gone on to accept donor hearts and kidney allografts. Another method of achieving transplant tolerance involves intrathymic injection of donor cells. These cells survive in the immunologically “privileged” thymus and cause production of maturing T cells that are tolerant of the donor alloantigen.^{101,102} All of these methods take advantage of the central mechanism of tolerance induction and rely on the phenomenon of clonal deletion.

Anergy

For a T cell to become optimally activated, it requires a second, independent costimulatory signal in addition to the primary signal that is generated through contact between the TCR and the MHC. When T cells are stimulated in the absence of these signals, they can become functionally nonresponsive to repeated stimulation with antigen and are termed anergic.¹⁰³

Two major costimulatory interactions that take place between a T cell and antigen-presenting cell involve CD28/B7 and CD40L/CD40 pathways.^{104,105} There has been considerable interest recently in trying to block these pathways. Anergy is not automatically maintained once it is induced, and the continual presence of antigen has been shown to be required to maintain tolerance.^{106,107} Tolerance relying on anergy may also be a precarious state. It can be broken by infection and inflammation.^{108,109}

The blockade of these second signals uses antibodies (CD40, CTLA4) to specific receptors (CD40R, B27) to induce a peripheral form of tolerance. The concept that the presentation of antigen in certain situations could down-regulate the immune system is not new. Before the discovery of these receptors, previous investigators had noted that donor-specific blood transfusions appeared to increase graft survival, theoretically by presenting MHC antigens in a limited fashion and inducing a state of T-cell anergy rather than activation.¹¹⁰ The interruption of the CD40 and CD28 pathways (costimulatory blockade) at the time of transplantation has been demonstrated to induce a state of tolerance in several rodent models without any significant infectious or malignant complications. However, the application to the primate model has not replicated these results and has demonstrated only prolongation of allograft survival rather than tolerance. Several modifications of this technique are under study and may lead to a longer-lasting state of donor-specific T-cell anergy. Other methods of peripheral tolerance induction include donor antigen-presenting cell depletion or modification and anti-CD4 antibody to block T_H-cell function.¹¹¹ These peripheral methods of tolerance induction have not been as effective as the central mechanisms.

Immune regulation by regulatory cells

A role for active suppression in inducing and maintaining tolerance had been suggested by a number of studies. However, previously there had been an inability to propagate these cells *in vitro* or to identify these cells *in vivo*. This made it difficult to identify the mechanism involved. Thus, the mechanism of suppression remained controversial, despite a number of transplantation models that provided functional evidence for the existence of such cells.^{112–114} Significant progress has been achieved in the characterization of these suppressor/regulatory cells with the identification of a T-cell population that coexpresses CD4 and CD25 surface antigens.¹¹⁵

These CD4+ CD25+ T cells occur naturally in the thymus and represent a functionally distinct subpopulation of T cells. These cells have been characterized as a suppressive T-cell population that promotes tolerance to self and foreign antigens.¹¹⁶ In 2003, three independent groups showed that Forkhead box protein 3 (Foxp3), a nuclear transcription factor defective in the multisystemic autoimmune disease IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome),¹¹⁷ was expressed in CD4+ CD25+ T regs.^{19–21} Foxp3 was shown to correlate with suppressive activity and appears to regulate the expression of several cell surface molecules previously used to identify T regs, such as CTLA-4, GITR, and CD25 itself.²⁰

T regs can also be defined by their origin and are currently divided into two physiologically distinct groups. There are

the so-called natural (n) T regs that are thought to be generated intrathymically upon presentation of self antigen by thymic epithelial cells. The other category is the adaptive or induced (i) T regs that appear to be produced in the periphery, after an encounter with either self or foreign antigens. Several groups have confirmed that mature animal and human T cells can be converted from CD25– to CD25+ or Foxp3– to Foxp3+ in different experimental settings.^{30–34} Although both types of T regs share similarities, nT regs seem to have more stable expression of Foxp3.³⁵

An additional finding has been that individual populations of T regs may not only have different origins, but exhibit significant plasticity in the expression of their phenotype (much like T_H cells) depending on the cytokine milieu. Recent rodent data have shown that, after *ex vivo* manipulation of CD4+ CD25+ T regs with either Th1 or Th2 cytokines, the function of the cells can be quite different.³⁶ In certain circumstances these T regs (CD25+Foxp3+) can not only trigger the expansion of Th17-producing T cells but can also differentiate themselves into Th17 T cells *in vitro* upon stimulation with allogeneic antigen-presenting cells.^{37,38,118}

Several articles have reported a high proportion of circulating and intra-graft T regs in tolerant/stable patients in renal as well as liver and lung transplantation. In contrast, recipients with chronic rejection had significantly fewer T regs and lower levels of Foxp3 transcripts than clinically tolerant patients and healthy individuals. Mechanistic studies in renal transplant recipients confirmed that donor hyporesponsiveness was abrogated by depletion of CD4+ CD25+ high T cells. Thus, a technique to produce T regs could increase the durability of tolerance and perhaps be employed along with other tolerance induction techniques.

Transplantation in plastic surgery

Skin

Skin autograft

Autologous skin grafts can be of either full or partial thickness. The full-thickness skin graft gives an excellent cosmetic result with limited graft contraction but has the disadvantage of unreliable graft “take”. The amount of full-thickness skin graft is also limited by donor site availability. In cases in which large areas are to be covered, split-thickness skin grafting is used and is the most commonly practiced form of tissue transplantation in plastic surgery. It has the advantage of large available donor areas and better graft take but the disadvantage of increased graft contraction. Expansion of the split-thickness skin graft by meshing with expansion ratios from 1:1.5 to 1:9 is both useful and often essential in large burns.

Donor sites for split-thickness skin graft harvest may be limited in patients with extensive burns. This lack of available tissue has spurred the development of alternatives to conventional skin graft. Keratinocytes can be grown in culture with the ability to expand the available tissue 10000-fold.¹¹⁹ This technique has been applied in the treatment of large thermal injuries as well as leg ulcers and other benign conditions.¹²⁰ The reported disadvantages with cultured keratinocytes are

that they are more sensitive to bacterial contamination than are split-thickness grafts, and take has been reported to be poorer in comparison to meshed graft.¹²¹ They also blister spontaneously, are more susceptible to minor trauma, and contract more than do split-thickness skin grafts.¹²² These effects are related to a poorly developed dermis–epidermis junction.¹²³ The lack of a dermal component in these autologous grafts was overcome by a combination of cultured autologous keratinocytes and allogeneic dermis.¹²⁴ The technique has had favorable reports in patients with large burns, but the problem of an allogeneic dermis remains. Development of an acellular or “artificial” skin (Integra) consisting of dermal components, collagen, and a glycosaminoglycan overlaid with a sheet of Silastic addressed this antigenic problem.¹²⁵ A disadvantage of this approach is the need to skin graft the “dermis” after removal of the outer Silastic dressing. This has been superseded by seeding the graft with keratinocytes at the time of initial application.¹²⁶

A skin substitute containing allogeneic or xenogeneic structural proteins and ground substance seeded with autologous cells has also been described; it is composed of cultured autologous fibroblasts populating the dermis and cultured autologous keratinocytes covering the dermis.¹²⁷ These collagen gel dressings share the disadvantage of autologous cell culture in that cells require time in culture for expansion to usable numbers. An acellular dermal allograft available commercially is AlloDerm (LifeCell, Branchburg, NJ). A tissue-engineered living allogeneic dermal construct, Derma-graft (Advanced Tissue Sciences, La Jolla, CA) consists of human neonatal dermal fibroblasts seeded on to a synthetic mesh.¹²⁸ It has compared favorably with skin allograft as a temporary cover for severe burn wounds.¹²⁹ Another substitute is Graftskin (Organogenesis, Canton, MA), which is composed of a type I bovine collagen matrix seeded with allogeneic human fibroblasts and overlaid with allogeneic human keratinocytes.¹³⁰

Skin allograft

Skin allografts have been found to be beneficial in large burns either in combination with autograft or in isolation.^{131–135} Techniques such as use of widely meshed autologous split-thickness skin grafts with a meshed allograft overlay have been shown to have improved healing in comparison to autologous mesh alone. The availability of skin allografts has increased with the formation of regional tissue banks. Allogeneic skin may be frozen and banked in a manner that allows it to remain viable for a protracted period. Preservation with glycerol reduces the antigenicity of skin allografts and prolongs their survival.¹³⁶ Glycerol-treated grafts have been used in burn centers as coverage for burn wounds before autografting¹³⁷ or as composite grafts overlying widely meshed autografts.¹³³ However, the use of these grafts has been reported to lead to the production of antibodies that may inhibit the possibility of future VCA.

Factors that limit widespread use are that harvesting and banking services are not uniformly available, demand outstrips supply, and there is a small but significant risk of disease transmission. Cytomegalovirus infection, hepatitis, and human immunodeficiency virus infection have been reported in burn patients after cadaveric skin use.¹³⁸ Cultured allogeneic keratinocytes have also been used as a temporary

covering and will survive with immunosuppressive drugs.¹³⁹ Growth in culture is possible pre-emptively in burn treatment, but skin allografts are susceptible to rejection in addition to the problems associated with cultured autografts.

Skin xenograft

Porcine xenograft has been used as a temporary dressing in large burns with seeding of autologous grafts beneath it.¹⁴⁰ The application of xenogeneic dermis has also been found valuable in preparing a wound for subsequent grafting by stimulation of granulation tissue formation. The acellular artificial skin described by Burke *et al.*¹²⁵ uses a bovine collagen dermis that recipient fibroblasts repopulate. Xenogeneic tissue has limited uses in skin grafting because its cellular components are susceptible to hyperacute rejection.

Bone

Bone autograft

A series of basic histologic events follows transplantation of a bone autograft.¹⁴¹ After transplantation, the graft is surrounded by hematoma; the inflammatory cascade follows in which infiltration of inflammatory cells is followed by ingrowth of new vessels with removal and replacement of any dead or necrotic tissue. Nonvascularized grafts undergo necrosis, most of the osteocytes in the graft die, and only those on the surface that re-establish blood supply survive. The remainder of the graft is infiltrated by blood vessels from the recipient site and is repopulated by recipient osteocyte mesenchymal stem cells. Vascular ingrowth in cortical bone occurs through pre-existing haversian canals. There is an initial increase in osteoclast resorption activity, which increases the porosity and decreases the strength of the graft. Cancellous grafts are more rapidly revascularized by virtue of their open structure within 2–3 days. By comparison, revascularization of cortical grafts may take up to 2 months. The process in which vascular tissue invades the graft, bringing with it osteoblasts that deposit new bone, has been termed creeping substitution. Cortical bone shows incomplete resorption of necrotic bone, and the final graft mixture of living and dead bone does not approach the strength of a cancellous graft.¹⁴¹ Vascularized bone graft obviates the reparative phase of a nonvascularized graft and does not require a well-vascularized recipient bed. Biomechanically, vascularized bone grafts are superior to nonvascularized grafts.¹⁴²

Reconstruction of larger bone defects is limited by available autologous donor sites. An alternative being investigated experimentally is that of autologous osteocytes expanded in culture and grown in the recipient on polymer scaffolds.^{31,143}

Bone allograft

The advent of well-organized tissue banks and improved methods of bone graft sterilization and preservation have allowed the clinical use of large bone allografts.^{144–147} The use of frozen bone allograft has become a common practice for the reconstruction of long-bone defects, with an estimated annual volume of more than 200 000 procedures in the US.¹⁴⁸ MacKewen is credited with the first clinical use of allograft bone in 1881, followed by Lexer, Parrish, and others.^{141,149–152} Few if any of the donor cells in the nonvascularized bone graft

survive. The remaining bone acts as scaffold for ingrowth of recipient mesenchymal stem cells (osteocyte precursors) that repopulate the donor scaffold by creeping substitution. The larger graft acts as a mechanical spacer; because of slow union, long-term fixation is required, and as a result, the graft is susceptible to stress fracture and loosening of metal fixation devices. Large joint replacement has been in clinical practice for some time with mixed results. Parrish reported 50% collapse with use of frozen whole bone ends in 21 cases.¹⁵¹ Mixed results with use of large or smaller shell grafts for joint resurfacing or replacement after surgical excision have been reported.¹⁵³⁻¹⁵⁵ In craniofacial surgery, freeze-dried bone allografts have been used in midface advancements.¹⁵⁶ The infection rate was high, at 22%, but osteotomies healed in all patients. Bone allograft with autogenous bone chips has been reported in mandibular reconstruction.^{157,158} In hand surgery, bone allograft has been used to reconstruct defects after benign tumor removal and for traumatic or congenital defects.^{159,160} No major complications were reported, such as infections, fractures, or nonunion.

Vascularized allogeneic bone is susceptible to immunologic rejection.¹⁶¹⁻¹⁶⁴ The humoral and cellular response generated has a time sequence similar to that generated by any other allogeneic tissue.¹² Although individual bone cells express antigens, the predominant immunogenic cell in a bone allograft is thought to be bone marrow-derived.¹⁵⁰ Removal of marrow as in irradiation or by replacement with recipient marrow has been shown experimentally to prolong allograft survival.^{165,166} There has been a limited series of vascularized clinical allogeneic bone transplants (knee transplants) performed first under single-agent (cyclosporine) immunosuppression and later employing triple-drug immunosuppression.^{167,168} All of these grafts were lost within the first 56 months, regardless of the immunosuppression chosen. One confounding factor may be the addition of a vascularized skin paddle for immune monitoring that may actually increase the immunogenicity of the transplant.

Cartilage

Autologous cartilage

Cartilage is composed of chondrocytes within lacunae dispersed throughout a water-laden matrix. There are histologically three types: hyaline cartilage, elastic cartilage, and fibrocartilage. The matrix is composed predominantly of proteoglycans and type II collagen. Cartilage has no blood supply and relies on diffusion of nutrients and oxygen through the matrix. Chondrocytes, in contrast to osteocytes, have little reparative ability and heal by forming fibrous scar tissue.¹⁶⁹ The viscoelastic properties of the matrix provide cartilage with a “memory” in that it returns to its original shape after deformation; the variable water content in matrix causes a balanced tension within it and thus maintains its three-dimensional shape.

Cartilage autograft is used regularly for nasal, auricular, craniofacial, and joint surface reconstruction.¹⁷⁰⁻¹⁷² There are limited potential donor sites. Development of experimental tissue-engineering techniques has allowed the expansion of chondrocytes in culture to increase their numbers. These cells are seeded on to biodegradable polymers to form new autologous cartilage.^{31,143,173,174} Injectable polymer systems allow

delivery of autologous cartilage by needle, transcutaneously, or arthroscopically.¹⁷⁵⁻¹⁷⁷

Cartilage allograft

Chondrocytes express HLA antigens on their surface and are immunogenic.¹⁵³ The matrix is only weakly antigenic.¹⁷⁸ Surgical scoring or dicing with resultant exposure of allogeneic cells has been shown to hasten reabsorption of allogeneic cartilage.¹⁷⁹ Cartilage allografts have been used for applications similar to those of autologous cartilage.¹⁸⁰ Allogeneic cartilage can be either preserved or fresh. Preserved cartilage has the advantage of a more abundant supply without the risk of infection that is associated with the use of fresh cartilage.¹⁸¹⁻¹⁸³ Cartilage allograft, usually with irradiation pretreatment, has been used for volume augmentation in the facial skeleton. Despite initial good results in a large number of patients,¹⁸³ long-term data suggest a high rate of resorption.¹⁸⁴ Whether this is immunologically based or because preserved grafts tend to contain no viable cells is a matter for debate.¹⁸⁵ It has also been noted that smaller grafts are less susceptible than larger ones to graft volume loss.

Cartilage xenograft

Bovine-derived cartilage xenografts are susceptible to xenogeneic mechanisms of rejection, which results in a generally poorer outcome in comparison to either allogeneic or autogenous cartilage grafts. Attempts to modify these xenogeneic responses by altering the graft's immunologic stereotactic structure have been reported as being beneficial.¹⁸⁶

Nerve

Nerve autograft

The best clinical outcome after nerve transection is achieved with primary repair. Extensive injuries with a nerve gap require a nerve graft to achieve nerve repair without tension. The nerve graft undergoes the same degenerative process as in the distal recipient nerve after division.¹⁸⁷ What remains of the nerve graft is a myelin sheath with Schwann cells that act as a biologic conduit for the regenerating axons. The most common type of nerve graft is the interfascicular nerve graft, which joins fascicular groups to their distal matching group with an interposition nerve graft.¹⁸⁸ Other types in modern practice are fascicular nerve grafts (limited by matching proximal to distal fascicle) and vascularized nerve grafts, thought theoretically to be of advantage, although not of proven benefit clinically.¹⁸⁹ Other “conduits” have been used as nerve grafts,¹⁹⁰ such as silicone tubes seeded with Schwann cells, autologous vein, freeze-fractured autologous muscle, and pH tubes.¹⁹¹ Artificial conduits have demonstrated improved outcome when they have been seeded with autologous Schwann cells. None of the conduits to date has been found to be superior to nerve autograft.

Nerve allograft

Nerve autograft has a limited number of donor sites. In large nerve defects, nerve allograft has been used in a small number of patients. Immunologic rejection of nerve allograft can be prevented experimentally with immunosuppressive

drugs,^{192,193} and immunosuppressed axons will traverse the allogeneic graft in rodents^{194,195} and nonhuman primates.¹⁹⁶ Immunosuppression needs to be administered only while the recipient axons traverse the allograft and can then be terminated.^{197–199} Mackinnon *et al.* reported a series of 7 patients who underwent nerve allografting in the upper and lower extremities.^{190,200} Immunosuppression was stopped 6 months after nerve regeneration across the allografts. All but one patient demonstrated return of motor and sensory functions.

Limb and composite tissues

Microvascular autogenous tissue transfer is a well-established reconstructive modality. Available donor sites limit the autologous transplants of tissue. In addition these donor sites can be associated with potential morbidity. The ability to use allogeneic limb or vascularized composite tissues such as skin, subcutaneous tissues, muscle, bone, blood vessel, and nerve has greatly expanded the realm of reconstructive surgery. Extensive skeletal and soft-tissue defects or even whole limbs have been replaced. However, nonautogenous tissue is susceptible to immunologically mediated rejection with subsequent graft loss, and prolonged immunosuppression is the only way at present to attain long-term allograft survival. To make composite tissue transplantation clinically feasible, consideration should be given to its technical, functional, and immunologic aspects.

Technical considerations

Transplantation of vascularized limb or composite tissues was made possible by the microsurgical techniques first developed by Carrel and Guthrie in 1906.^{201,202} Microvascular anastomoses and revascularization have become routine practice in large centers, with success rates in excess of 90%.^{203,204} In contrast to acute traumatic cases, such as replantation, allogeneic transplantation has been performed in elective settings after appropriate preparation, such as preoperative angiography and donor selection. The operative techniques are based on the current advances in bone, tendon, and nerve repairs.

Functional considerations

Normal wound healing and bone growth occur in transplanted composite tissue allografts after experimental transplantation in various animal models.^{26,205} Return of neuromuscular function has been observed in limb allografts of animals treated with immunosuppression,^{206,207} including those in the primates,^{208–210} while in clinical hand transplants both motor and sensory recovery have been reported.^{5,211,212} Thus, functional recovery after allogeneic transplantation appears to follow the same principles as in nontransplant situations and is influenced by the recipient's age, systemic factors, and associated local injuries.

Immunologic considerations

A limb or vascularized composite allograft consists of multiple discrete tissue components, such as skin, subcutaneous tissue, muscle, and bone, and each tissue has been shown to be strongly antigenic.¹⁰⁶ Both animal data and the current clinical human experience have confirmed the need for significant

host immunosuppression to prevent allograft rejection. The potential adverse effects of indefinite, multiple-agent immunosuppression are difficult to justify in the opinions of many for a surgical procedure aimed at improving quality of life.^{14,213} This debate over the risk–benefit balance has continued since the first successful human hand transplantation. However, both the proponents and critics of the current transplants agree that significant reduction of host immunosuppression, and particularly tolerance induction to the allografts, would help achieve widespread clinical application of composite tissue allografts.

Experimental limb transplantation

Limb allograft transplantation is possible experimentally with different immunosuppressive regimens.^{205–207,209,214–222} Immune modulation techniques that decrease the antigenicity of specific components of a limb allograft were shown to prolong survival.¹⁶⁶ Although sporadic incidents of tolerance have been reported after cessation of immunosuppressants,^{216,223} long-term immunosuppression was generally necessary to prevent allograft rejection. Combination therapy with cyclosporine and MMF was more effective than monotherapy.²²⁴ Although rat models provide important information on limb allograft transplantation, the rodent immune system is fundamentally different from that of the human. A large animal model such as a canine, pig, or primate offers a much closer analogy to the human immune system.

Ustuner *et al.* reported transplantation of a radial forelimb osteomyocutaneous flap between size-matched outbred swine with use of a daily cyclosporine, MMF, and prednisone oral regimen.²²³ Of the eight swine, two sustained severe rejection, three demonstrated mild to moderate rejection, and three were free of rejection at the termination of the experiment at 90 days. No drug toxicity was evident in serum hematologic and chemical parameters of immunosuppressed animals. The Louisville group also examined the use of FK506, MMF, and prednisone in the same swine model.²²⁵ Five of nine animals that survived to the study end at 90 days were noted to be free of rejection. However, this combination of immunosuppressants resulted in significant mortality and morbidity, including abscesses, diarrhea, weight loss, and pneumonia.

Lee *et al.* sought to achieve host tolerance to musculoskeletal allografts through matching of the MHC antigens between donor and host swine with only a 12-day course of cyclosporine.²²⁶ Allografts from MHC-mismatched donors treated with cyclosporine and allografts from MHC-matched (minor antigen-mismatched) donors not treated with cyclosporine were rejected. However, allografts from MHC-matched donors treated with 12 days of cyclosporine showed no evidence of rejection until sacrifice up to 47 weeks after transplantation. Thus, genetic matching may alleviate the need for immunosuppression after limb transplantation. MHC matching can be extended beyond family members, for example, as the National Bone Marrow Registry exists to match MHC of unrelated individuals.

More recently, Kuo *et al.* demonstrated that the use of mesenchymal stem cells combined with bone marrow transplantation, irradiation, and short-term immunosuppressant therapy could prolong CTA survival (>200 days) in a swine hind-limb model.²²⁷ The authors suggested that the regulatory

activity of the mesenchymal stem cells might be contributing to the prolongation seen in this model.

The primate model offers the closest imitation to human limb transplantation in anatomy and immune system. In the 1980s, four studies of limb allograft transplantation were performed on nonhuman primates.^{209,210,222,228} All of the studies involved the transplantation of a hand and use of high-dose cyclosporine and steroids. Many of the animals suffered multiple infectious complications, with some succumbing to fatal malignant neoplasms resulting from high levels of immunosuppression. Nonetheless, few primates demonstrated prolonged survival of their allografts. These studies confirmed the existing rodent and canine data that cyclosporine monotherapy is ineffective in preventing limb allograft rejection, even at toxic doses. Few allografts survived long enough for functional recovery to be ascertained. More recently, Barth *et al.* performed heterotopic transplants of composite facial subunits consisting of skin, muscle, and bone in mismatched *Cynomolgus* macaques.²²⁹ They attempted to use high-dose tacrolimus monotherapy via continuous intravenous infusion for 28 days, which was then tapered to daily intramuscular doses. They had initially hoped that this limited course of high-dose tacrolimus would lead to tolerance, as had been observed in the swine kidney model. Although this protocol of tacrolimus monotherapy did provide prolonged rejection-free survival of the allografts, it was associated with the development of a high frequency of donor-derived post-transplant lymphoproliferative disorder tumors. No study has been performed in primates with combination immunosuppressant therapy. The application of such a regimen could provide insight into nerve regeneration, bone healing, and ultimate recovery of function. Cendales's group examined the possibility of using belatacept in combination with tacrolimus in a primate model of hand transplantation. Compared to tacrolimus, the addition of belatacept improved rejection-free allograft survival.²³⁰ They also found that when they combined belatacept with rapamycin there was unacceptably high rates of wound failure in skin-containing transplants.

Hand transplantation

Currently, clinical hand transplantation remains an experimental procedure, and the long-term outcomes of this innovative procedure are still being determined. In the current era of immunosuppression, there are 107 known transplanted hand/upper extremities in 72 patients (Table 32.3).^{5,11,211,212,231–235} The results thus far have demonstrated that hand transplantation is technically feasible and the outcomes are promising, with patients reporting varying degrees of return of function. The support for the application of hand transplantation from hand surgeons has been strongest for those patients who have lost both hands.¹⁴ While most programs continue to perform transplants under their local institutional review board guidelines, several programs have proposed bilateral hand transplantation as the standard of care for bilateral amputation but no center has performed a transplant without an IRB protocol. The support for unilateral transplantation has been much lower from the surgical community. However, patients who have undergone unilateral hand transplants have reported the restoration of self as well as return of function. Thus, while function is a critical outcome for the

measurement of success, the restoration of the patient's well-being and sense of self must also be considered in the evaluation of hand transplantation.

The major issues in hand transplantation are the need for maintenance immunosuppression and the evaluation of the functional outcomes of the transplants.^{236,237} There are well-known risks to the transplant recipient related to the use of chronic immunosuppression. These include complications such as an increased susceptibility to opportunistic infections, renal dysfunction related to the use of calcineurin inhibitor-based medications (tacrolimus and cyclosporine), and an increased incidence of malignancies. In addition, despite the use of modern immunosuppression regimens, the majority of the transplants experience episodes of acute rejection and will likely face chronic rejection. The functional outcomes have been, for the most part, favorable but the current challenge remains to improve nerve recovery and the restoration of function of the intrinsic muscles of the hand.

Immunosuppression and transplant survival

The emergence of hand transplantations and the field of reconstructive transplantation have not corresponded to any recent breakthrough in transplantation immunology. It is clear from the 1-year survival data of such highly antigenic transplants as the lung and intestine that the current potent immunosuppressant drugs can prevent the fulminant rejection of even highly antigenic tissues, as long as sufficiently high doses of different agents are used.^{238,239} This has been replicated in the hand transplantation literature as there has been an excellent 1-year survival of the transplants.⁵ Thus, the critical issue continues to be how much immunosuppression, and lifelong morbidity, can be justified for a nonlife-saving procedure.

There is significant variability in medications employed to maintain the hand transplants, making it difficult to conclude the superiority of one immunosuppressive regimen over another. This type of conclusive evidence will only be derived from prospective, randomized clinical trials. Therefore, as this technique expands, it will be important to organize multicenter trials to determine the best practice for the use of immunosuppression after hand transplantation.

Currently, the majority of the transplant programs have employed the use of an induction agent such as IL-2 receptor blocker (basiliximab), ATG, or the anti-CD52 monoclonal antibody (alemtuzumab). There was an initial trend towards using more anti-CD52 monoclonal antibody in hand transplant patients but the use of this drug has decreased more recently.²⁴⁰ The Louisville group initially used the IL-2 receptor blocker (basiliximab) on its first 2 patients as the sole induction agent but then switched to alemtuzumab on all subsequent patients,²¹¹ while the Lyons group relied solely on ATG on all its patients.²¹² More recently, groups at the Johns Hopkins University and the University of Pittsburgh have implemented a program to move beyond the current three-drug regimen. They have employed alemtuzumab induction therapy as an integral part of their "Pittsburgh/Johns Hopkins University protocol" that uses donor bone marrow infusion in combination with tacrolimus monotherapy in an attempt to reduce the amount of chronic immunosuppression needed and thereby improve the risk-benefit balance.

The most common maintenance immunosuppressive regimen used in hand transplantation has been a continuous administration of low-dose steroid with tacrolimus, and MMF. However, over time several teams have changed from tacrolimus to sirolimus treatment to avoid the side effects, such as hyperglycemia or renal insufficiency.⁵ In some cases, the teams attempted to decrease the immunosuppressive medications and wean or eliminate steroids from the regimes. However, while such strategies have been successful in the renal transplant literature, in these hand transplants evidence of myointimal hyperplasia has been noted. In addition, one of the hand transplants in Louisville was lost due to what appeared to be chronic rejection after being maintained on reduced immunosuppression protocol.^{231,241} Thus, it may not be possible simply to transfer protocols that have demonstrated results in renal transplantation directly to hand transplantation.

Measuring outcomes in hand transplantation

The accurate evaluation of the functional outcome of the hand transplant patient is critical to determining the value of this

nonlife-saving transplant. Currently, there is some variation in the tools that are employed to quantify the function of the hand transplant. While the Louisville group has reported much of the functional outcomes in publications based on the Carroll test (a well-validated test that evaluates the patient's ability to perform activities of daily life that involve the upper limb),²⁴² the International Registry on Hand and Composite Tissue Transplantation bases its functional outcomes on its own Hand Transplantation Score System (HTSS).^{5,211} This evaluates six aspects of the hand transplant: (1) appearance (15 points); (2) sensibility (20 points); (3) motility (20 points); (4) psychological and social acceptance (15 points); (5) daily activities and work status (15 points); and (6) patient satisfaction (15 points). A total result of 81–100 points is graded as an excellent outcome, 61–80 as good, 31–60 as fair, and 0–30 as poor. The University of Pittsburgh bases its evaluation of patients on measurement of active range of motion, passive range of motion, grip strength, pinch strength, and two-point discrimination. They also use the Semmes–Weinstein evaluation to document the sensory return of the transplants. Early results from this group show that all their patients

demonstrate sustained improvements in motor function and sensory return correlating with the time after transplantation and level of amputation.

All of the hand transplantation programs have used the Disabilities of the Arm, Shoulder and Hand (DASH) score to evaluate patients post-transplant.²⁴³ The DASH Outcome Measure is a 30-item self-report questionnaire designed to measure physical function and symptoms in people with any of several musculoskeletal disorders of the upper limb. The tool is a single reliable instrument that can be used to assess any or all joints in the upper extremity.

The longest follow-up available is from the second hand transplant performed by the group in Louisville; the patient is now more than 18 years postoperative with a functioning hand. In a recent article, the group in Louisville reported detailed outcomes of the first two American hand transplant recipients at 8 and 6 years post-transplantation.^{211,231} Both patients have allograft survival, with improvements in intrinsic muscle activity, total active motion, and return of functional grip, pinch strength, and sensibility. The latest Carroll test scores, which measure patients' ability to perform tasks requiring a combination of mobility, motor function, and sensation, are fair for patient 1 (72/99) and fair for patient 2 (55/99). These Carroll test scores exceed the expected results of 20–30 of 99 that would be achieved with a prosthetic hand. The first patient's Semmes–Weinstein monofilament sensation testing is in the normal range for all fingertips, and the patient has shown improvement in both static two-point discrimination and moving two-point discrimination over previous testing. Touch localization, stereognosis, and temperature and vibration sensation have also returned. The second patient has not demonstrated a similar return of sensation through year 6; however, in 2008, his protective sensation was noted to have returned. In a more recent update they reported the results of their third patient in which they stated the Carroll score was 57 at the yearly checkup. The range of motion with active digital motion was approximately 45% of normal. Sensory evaluation showed advancement of Tinel's sign to fingertips, diminished protective function, and light touch localization in the index, ring, and small fingers only.

The International Registry reported that, based on the HTSS scale, the majority of patients demonstrated good results from the hand transplant procedure.⁵ They noted that from a functional point of view there was good recovery in the majority of the transplanted hands. However, the recovery of motor function was limited to the larger muscle groups but they often enabled the patients to perform most daily activities. The level of satisfaction was slightly higher in the bilateral hand-transplanted patients when compared to unilateral patients. All of the patients developed protective sensation (31 patients analyzed with a minimum of 1-year follow-up) and 90% regained tactile sensibility. The time to development of distal sensory and motor recovery was correlated to the level of amputation. It was noted that the more distal the level of amputation, the faster the recovery of the transplanted hand. This finding has called into question the level at which to offer a hand transplant but currently there are no firm recommendations from any of the active groups.

Several of the groups included in the international registry analysis have also published individual reports. The group from Poland has recently published follow-up on two patients who have undergone successful hand transplantation.²³³ The

first patient was 3 years out at the time of publication and has demonstrated total active motion of fingers equal to 63% of that of his unaffected hand. His DASH score was reported as 95 and the patient returned to work 20 months after the transplant. The second patient was only 6 months post-transplant and scored 85 points on the DASH questionnaire. The surgeons reported that the Semmes–Weinstein monofilament test had documented 15 mm two-point discrimination and the transplanted hand grip strength reached 4 kg. This patient had also returned to a full-time job.

The Lyon group documented the late results of their two bilateral hand transplant patients.^{212,244} Both patients have recovered pain and cold sensations, without dysesthesia or cold intolerance. The first recipient, 6 years after transplantation when the paper was published, had a Semmes–Weinstein test that demonstrated sensitivity recovery on the right hand using 2.83–3.61 monofilaments and on the left hand using monofilaments between 3.22 and 4.08. The average two-point discrimination test was 6 mm on the right hand and 9 mm on the left hand. In contrast, the second patient's Semmes–Weinstein test demonstrated sensitivity recovery on the right side using 3.22–3.61 monofilaments and on the left side using monofilaments between 3.22 and 3.84. However, muscle strength was diminished in both patients. The first patient had bimanual grip strength of 12 kg and the second patient's grip strength was 4 kg on the right side and 8 kg on the left side.

While the authors from Lyon comment that manual dexterity evaluated using the Minnesota and Carroll test demonstrated a normal capacity for reaching, grasping, moving, positioning, and turning the objects, they did not provide scores for these tests. They did comment that the first recipient continued to have impairment to lateral pinch and bimanual grasp. The patients were, according to the authors, able to perform the majority of daily activities by the first year after transplantation. One of the two patients had returned to work.

Finally, the Innsbruck group has published an 8-year follow-up after hand transplantation.²⁴⁵ One of the most significant findings from this group is that patients can continue to observe improvement of their function and sensation even at years 4 and 5 after transplant. Their first patient demonstrated excellent recovery after bilateral hand transplantation. Eight years after transplantation, hand function in this patient was outstanding. He is able to use his hands symmetrically, performing all activities of daily life. The current DASH score is 34. The second patient was a forearm transplant who has experienced continuous improvement of motor function during the first 3 years and, according to the authors, has satisfactory hand function. The patient noted that the hand function is superior to that he had achieved with myoelectric prostheses. While the patient has noted recovery of hot and cold discrimination (at 6 months after transplantation), his overall sensitivity remains poor with no detectable two-point discrimination. Grip strength measured 6.8 kg on the right side and 5.5 kg on the left side. However, compared with results after hand transplantation, fine motor skills were slightly inferior in our forearm transplant patient. The third patient was still in the process of undergoing intensive outpatient therapy at the time of the publication.

The world experience in hand transplantation demonstrates the clinical utility of this emerging technique. However, there are many questions that are currently unanswered. These

questions surround the best use of immunosuppression and immunosuppressive regimens. It highlights the importance for future collaborations between centers to address best practice in the immunosuppression regimen. This review also reveals the need for continued collaborations between groups to standardize the way in which functional outcomes are measured so that case outcomes can be compared more easily.

Facial transplantation

A total of 37 face transplants have been performed (20 partial and 17 full face) from 2005 to December 2015 (Table 32.4).¹⁰ There are some discrepancies between actual transplantations performed and those reported in peer-reviewed journals, with some underreporting of the transplants performed. All of the patients have experienced rejection episodes but the majority of these have been successfully treated. These transplants have restored form and function in the majority of the patients.

Post-transplant malignancies have increased in incidence, and a total of six patients have died. The first face transplant patient, performed in Lyon, France, recently died secondary to non-small cell lung cancer likely related to her history of smoking. She also exhibited donor specific antigen that may have led to the rejection of her sentinel flap and later her lower face. The second face transplant patient died secondary to non-compliance with his medications. The other deaths were related to recurrent head and neck cancer and necrotizing infection after attempted combined hand and face transplant.^{246–248}

Future of transplantation in plastic surgery

The current strategy for the post-transplant management of composite tissue allograft is to treat them with well-established regimens of immunosuppression used in solid-organ transplantation. The majority of VCA transplant patients have been treated with an induction agent (such as ATG or alemtuzumab) and then maintained with up to three immunosuppressive medications (tacrolimus, MMF, and steroids). This has led to a high level of success in terms of initial graft survival. It has not prevented episodes of acute or chronic rejection. However, in order for the field of reconstructive transplantation to expand its indications beyond the current limited experience, techniques need to be designed either to significantly reduce or eliminate the need for chronic immunosuppression. The future direction of this field is heavily dependent on the development of innovative approaches to the use of immunosuppressive agents and tolerance induction protocols.

Many still regard the use of chronic immunosuppression to achieve transplantation of limb or a facial allograft difficult to justify clinically.²⁴⁹ Development of effective regimens to induce host tolerance without long-term immunosuppression, therefore, is essential to alter the risk–benefit balance. Such regimens may involve site-specific immunosuppression directed at the graft, monoclonal antibodies that block a particular step in the process of antigen recognition, or exposure to donor antigen with the introduction of hematopoietic stem cells either before or at the time of transplantation to establish a state of mixed chimerism.²⁵⁰

T-cell-depleting therapies have been effective at promoting graft acceptance and tolerance in several animal models.^{251,252} However, clinical translation of these protocols had not yielded significant progress until the introduction of the anti-CD52 monoclonal antibody, alemtuzumab (Campath-1H). CD52 is expressed on most T and B lymphocytes, NK cells and monocytes, and alemtuzumab rapidly depletes these cells with varying kinetics of repopulation. The initial clinical reports by Calne *et al.*^{90,91} suggested that the use of alemtuzumab in combination with low-dose cyclosporine in kidney transplantation could achieve a state of “prope” tolerance (graft acceptance with reduced immunosuppression). However, the use of alemtuzumab alone or in combination with deoxyspergualin led to 100% acute rejection.^{253,254} This demonstrated that alemtuzumab was not in itself tolerogenic. Its use as an induction agent has recently been demonstrated to significantly reduce the episodes of biopsy-proven acute rejection (14% versus 26%) when compared with thymoglobulin. However, there was no difference in survival, initial length of stay, and maintenance immunosuppression (including early steroid elimination).²⁵⁵ Attempts to use T-cell depletion agents such as alemtuzumab or ATG in the field of CTA have yielded similar results and highlight the need for additional strategies to allow for the reduction of immunosuppression.

VCA offers some unique advantages to develop innovative treatment protocols, such as continuous monitoring and adequate biopsy sampling of the graft by simple visual inspection of the skin, allowing for a timely intervention, treatment, and precise adjustments of immunosuppression on an individualized basis. In addition, some VCAs may contain varying amounts of donor bone marrow and a vascularized bone marrow niche, which could serve as a continuous source of donor cells, including bone marrow-derived stem cells. This has been demonstrated in certain experimental animal models to modulate the host immune response favorably. Hence, novel cell-based strategies to minimize immunosuppression or induce immune tolerance are particularly appealing in VCA.

The group at Johns Hopkins University introduced a strategy (while at the University of Pittsburgh), that takes advantage of the cellular depletion provided by alemtuzumab, combining it with a delayed donor bone marrow cell infusion. This technique had some reported success with living related kidney transplants; and appears to enable minimization of the maintenance of immunosuppression after liver, pancreas, heart and lung transplantation. They performed 8 hand/forearm transplants in 5 patients under this protocol at the University of Pittsburgh. The recipients have been maintained on a single immunosuppressive drug (tacrolimus) at low levels and continue to have increased motor and sensory function of their transplanted hands. Despite the combination of alemtuzumab induction and the donor bone marrow cell infusion, all of the transplants have experienced at least one episode of acute rejection that required additional treatment. However, acute episodes of skin rejection observed with this protocol were responsive to topical therapy alone in about 50% of cases or short courses of steroids. Both superficial and deep tissue biopsies as well as high-resolution ultrasound did not show any evidence of vascular myointimal proliferation as an indirect sign of chronic rejection. This bone marrow cell-based immunomodulatory protocol has been proven to be well tolerated and efficacious and has allowed hand/

forearm transplantation with low-dose tacrolimus monotherapy but does not appear to allow for the complete withdrawal of all immunosuppression. Unfortunately two of the patients had issues with compliance and have had their unilateral hand transplants removed. There are still three from the original group, and two more recent transplants have been performed at Johns Hopkins. Long-term data and follow-up, however, are still needed to confirm these findings.

The use of a single antibody may not have the ability to lead to tolerance of donor antigen. Thus the addition of other monoclonal antibodies, such as CD40 ligand, may be needed to produce a state of T-cell anergy to these antigens. It has been observed that full activation of T cells requires both cell–cell interaction and simultaneous delivery of costimulatory signals. A T cell that encounters foreign antigen in the absence of necessary cytokines fails to activate, which may lead to a state of tolerance.²⁵⁶ This mechanism is based on the blockade of CD28/CTLA4–CD80 and the CD40–CD40 ligand (CD154) pathways.^{257,258} Several nonhuman primate tolerance models to evaluate the effect of interrupting these critical pathways have demonstrated prolonged survival of renal allografts.^{259,260} It remains to be seen whether such strategies could allow limb transplantations to be performed with the ultimate cessation of immunosuppression.

However, it currently appears that T-cell depletion alone (with or without bone marrow) or the reliance on other antibodies is unlikely to lead to tolerance of organ allografts. Regimens that lead to the induction of mixed hematopoietic chimerism, however, have been shown to lead to tolerance of organ allografts in multiple preclinical studies.^{100,261–263} The strategy involves the use of bone marrow or stem cells to induce a state of mixed chimerism. Owen observed more than half a century ago that it is possible to induce tolerance by exposing the donor's bone marrow to the recipient's immune system before its maturity.²⁶⁴ Such fetal or neonatal induction

of tolerance for musculoskeletal allografts has been achieved in experimental swine and rodent models, respectively.^{265–267} Successful adaptation of this approach could even have therapeutic potential for congenital conditions. Similar application of mixed chimerism protocols could also lead to tolerance induction in adults.^{100,268} Foster *et al.* demonstrated that rodent mixed chimeras would accept syngeneic donor limb allografts.²⁶⁹ Huang *et al.* have used a minimally toxic protocol to generate mixed chimeras in the miniature swine with *in vitro* donor-specific tolerance while preserving immunocompetence to third-party antigens.^{270,271} Employing a similar strategy in the same model, Hettiaratchy *et al.* demonstrated tolerance to the muscle and bone portions of VCA allografts across a major MHC barrier.²⁷² In addition, case reports have shown tolerance to a kidney allograft in patients who received a bone marrow transplant from the same donor, sometimes years apart.^{273–275} However, the combination of most conditioning regimens combined with the infusion of bone marrow often results in GvHD. The greater the genetic disparity between the bone marrow recipient and the donor, the more likely the recipient will develop GvHD.

These findings led Sachs and colleagues to embark on a clinical trial using this approach to attempt to induce tolerance in patients with end-stage renal disease and advanced multiple myeloma using HLA-identical sibling donors.²⁷⁶ Six patients received cyclophosphamide, ATG, and thymic irradiation as well as cyclosporine (which was tapered off after 2 months) and subsequently followed by donor leukocyte infusions to improve graft-versus-tumor effects.^{277,278} All patients demonstrated initial engraftment of the donor marrow but the donor cell chimerism was lost in all of the patients except two. These two patients converted to full donor chimerism and had to be treated for GvHD. The other 4 patients maintained long-term renal function (up to >9 years) in the absence of immunosuppression. One of the 4 patients did have a single

rejection episode that was controlled by the transient use of immunosuppression.

The group recently modified its protocol to address the induction of tolerance in recipient kidneys from HLA-mismatched living donors. To reduce the risk of GvHD they now use an anti-CD2 monoclonal antibody (siplizumab or MEDI-507) for its T-cell depletion rather than ATG. Five patients received cyclophosphamide, MEDI-507, thymic irradiation, and cyclosporine.²⁷⁹ Occurrences of humoral rejection and engraftment syndrome led to the addition of rituximab and corticosteroids for the last 2 patients.²⁸⁰ Mixed chimerism was

transiently achieved in all patients but donor cells could not be detected after day 21 and GvHD did not develop. One patient lost his kidney graft as a result of an early and irreversible antibody-mediated rejection. In the other 4 patients, immunosuppression was successfully withdrawn during the first year post-transplant and normal renal function has been sustained for more than 3–6 years to date. The mechanisms underlying this operational tolerance are not fully elucidated. This model is also designed for living related transplants and in its current form would not be possible for VCA transplants.

Technology innovation in plastic surgery: A practical guide for the surgeon innovator

Leila Jazayeri and Geoffrey C. Gurtner

SYNOPSIS

- Plastic surgeons have historically been distinguished by their ability to innovate and should continue to maintain this competitive advantage.
- This chapter will familiarize the surgeon innovator with a systematic approach to innovation. This process includes idea formation, valuation, funding, intellectual property, institutional technology transfer, the FDA regulatory process, and conflicts of interest.
- Negative pressure wound therapy, acellular dermal matrix, and noninvasive body contouring are used to discuss the impact of innovation within plastic and reconstructive surgery.

Introduction

Innovation drives the advancement of medicine. Recent medical innovations, from evidence-based medicine and information technology to robotic and laparoscopic surgery, have revolutionized the practice of medicine. In the surgical arena, innovation has led to increasingly effective and less invasive therapies resulting in better patient care.

What separates invention from innovation? Invention is the formulation of new ideas for products or processes, while innovation creates the application of new inventions. In business, invention uses cash to create a product and innovation takes a product and creates cash. In medicine, invention is an attempt to create a solution to a clinical problem and innovation drives the solution to the bedside – analogous to the process by which translational research applies basic science to clinical problems.¹

Plastic surgeons, by trade, are innovators. We devise innovative solutions to difficult problems. Our competitive advantage lies in innovation. Unlike the neurosurgeon or cardiologist, we do not lay claim to any one part of the body.² In the hospital we are called upon for our creative solutions to the neurosurgeon's need for calvarial reconstruction, the cardiac surgeon's need for chest wall reconstruction, and the orthopedic surgeon's need for hardware coverage.

Our innovative spirit transcends beyond innovative surgical methods and encompasses innovation of novel technologies as well. Historically, microsurgery, distraction osteogenesis, tissue expansion, endoscopic plastic surgery, liposuction and laser technology have all served as platforms for expanding the scope of our practice, as well as expanding the scope of what we can offer our patients.³

The expansive breadth of plastic surgery exposes our field to multiple competing subspecialists. Dermatologists, otolaryngologists, ophthalmologists, obstetricians and internists are increasingly involved in aesthetic surgery. Similarly, general surgeons are competing for abdominal wall reconstruction, breast reconstruction, and wound healing. Otolaryngologists compete for head and neck reconstruction. Orthopedic surgeons compete for hand cases. Each of these fields involves important new innovations, and subsequently opportunities for patient care, research, and revenue. Aesthetic surgery is riddled with novel technologies including skin resurfacing techniques, noninvasive body contouring, injectables, and laser therapy. The attractive revenue stream in this cash-based field is obvious and draws in more and more competition. Similarly, abdominal wall reconstruction has been revolutionized by the introduction of new biomaterials. Breast reconstruction is changing with the introduction of new breast implants, fat grafting and dermal substitutes. The field of wound healing has dramatically changed with negative pressure wound therapy. Head and neck reconstruction has seen the introduction of bioabsorbable plates, screws and alloplastic bone substitutes, while PyroCarbon arthroplasty and artificial nerve conduits continue to expand the offerings of hand surgery. Innovation is the sustainable competitive advantage for plastic surgeons in this competitive clinical reality.

Today, however, the arena of medical innovation is far more complex than it was 50 years ago. There is more scrutiny from the US Food and Drug Administration, an exponential growth in the number of patents filed and more complexity in regulatory pathways for new medical products. In the setting of a healthcare and economic crisis, it is harder to

justify increased development expenses with increased competition for limited investment funds. When the surgeon is asked to innovate, he/she also faces a plethora of challenges unique to the surgeon innovator including conflict of interest concerns and navigating within the confines of the intellectual property claims of universities.⁴ The challenges faced by today's surgeon innovator are captured well by Machiavelli's *The Prince*: "There's nothing more difficult to plan, nor more dubious of success, nor more dangerous to manage than the creation of a new order of things. Whenever his enemies have the ability to attack the innovator, they will do so with a passion of partisans while others defend him sluggishly so that the innovator and his party are likely to be vulnerable." The enterprise of surgical innovation may receive little support and face many barriers, however it can create new technologies that may revolutionize a field and impact millions of patients. To overcome today's barriers to surgical innovation, we must create and use a systematic approach to translate ideas based on a human problem into a product that can change clinical practice.⁵ This chapter sets out to discuss a systematic approach to surgical innovation and gives a few examples of new technologies in our field.

The idea

Mark Twain said, "The name of the greatest of all inventors is accident." In 1957, Mason Sones accidentally injected the right coronary artery with dye, he immediately recognized the problem and pulled the catheter out while the injection of dye continued. He later said, "That day I realized that I had discovered something very important." He then went on to refine the technique that led to coronary angiography. On the other hand, Plato's frequently cited proverb, "necessity is the mother of invention" hints that innovation certainly does not need to rely on an accidental discovery.

Today, there are calculated and systematic innovation paradigms that start with the identification of a clinical problem. The problem should be an unmet clinical need. The scientific knowledge in the arena and the limitations of the current solutions should then be explored. The clinical problem can be taken to the laboratory or into multidisciplinary think boxes where a solution is systematically developed, with the hope of translating it back to the operating room. Robert Frost thought that ideas are feats of association, "Having what is in front of you brings up something in your mind that you almost didn't know you knew." This paradigm of discovery may describe why the majority of surgical devices are rooted in the ideas of observant surgeons. The timeless story of Dr. Thomas Fogarty's development of the Fogarty catheter started with a defined clinical problem and was assisted with "feats of association." Fogarty was a scrub technician and witnessed acute limb loss as a result of surgery to remove blood clots. As a medical student of the University of Cincinnati, he started to work on a solution to the clinical problem he had identified years previously. In his garage, he developed a balloon on the tip of a catheter that could be inserted through a small access incision and passed through the artery beyond the blockage. Once past the blockage, the balloon could be inflated and the clot dragged out of the artery. His ability to invent and prototype this novel device was perhaps facilitated by his prior association with surgical tools as a scrub

technician. He met much criticism from his mentors but went on to patent the balloon catheter, built the device in his garage, and worked tirelessly to have the catheter adopted by vascular surgeons. The Fogarty catheter has since revolutionized vascular surgery and led to a platform for innovations in minimally invasive techniques.

Whether accidental or systematically created, the idea behind an innovation can lead to the development of two broad categories of innovations: a novel method or a novel device. Because the majority of the chapter discusses medical devices, we will briefly discuss the innovation of novel methods. Delos Cosgrove describes his idea for a novel surgical method: "Several years ago, in preparation to perform aortic valve replacement, I found the ascending aorta entirely calcified and both femoral arteries occluded. Recognizing the danger of cannulating either one of these vessels, I raised the patient's arm to expose the axillary artery, which I used as the cannulation site. The aortic valve replacement was successfully performed."⁶ Bruce Lytle expanded this idea and refined the process of cannulating the subclavian artery for this problem. Substantial changes to a surgical intervention are reviewed by the Institutional Review Board (IRB), funded through academic sources, and described in new academic publications and presentations. The surgical community generally shares new methods without recovering royalties for the benefit of patients, even though novel surgical methods can be patented if desired.⁷

Determining the value

Value is the subjective relationship between the perceived benefit and perceived cost of a product or service.

$$\text{Value} = \frac{\text{perceived benefit}}{\text{perceived cost}}$$

As physicians, we are constantly assigning value to our therapies as a means of deciding how to provide medical care. We define the value of a given therapeutic intervention as the potential benefit to the patient in relation to the potential risk. Based on the risk-benefit ratio, we decide to proceed with or abandon a given therapy. Similarly, as surgeons we define the value of a surgical innovation as the potential benefit to the patient in relation to the potential risk. Based on the risk-benefit ratio, we decide to adopt or not adopt an innovation. In today's healthcare arena, before any novel surgical device is even available for use at the patient's bedside, its commercial value must be demonstrated. The commercial return on a device must outweigh its development risks in order to have a realistic chance of having the device available for patient use. To understand the value of an innovation, it is important to understand the perceived benefit the innovation has on (1) patient care, (2) technology, and (3) commercial impact (Box 33.1). We will review some of the terms used to describe an innovation's perceived benefit in these arenas.

The impact an innovation has on *patient care* can be described as revolutionary or incremental. A *revolutionary innovation* has a significant impact on patient care where an *incremental innovation* has a smaller effect. Consider the revolutionary impact of the endograft for repair of abdominal aortic aneurysms (AAA). The technique of using

BOX 33.1 Determining the value of an innovation

Impact on patient care

- **Revolutionary innovation:** significant impact on patient care, e.g. endovascular repair of AAA
- **Incremental innovation:** small effect on patient care, e.g., reiteration of laparoscopic dissector

Impact on technology

- **Enabling innovation:** serves as a platform for further developments within a field, e.g., liposuction
- **Refining innovation:** marginally improves upon available technology, does not lead to significant technology change, e.g., ultrasound and power-assisted liposuction

Impact on market share

- **Disruptive innovation:** supersedes industry leaders and takes over their market share, e.g., percutaneous transluminal angioplasty for interventional cardiology
- **Sustaining technology:** an improvement, usually by an industry lead, to maintain growth in the market, e.g., cardiac stent for interventional cardiology

a transfemoral intraluminal graft for repair of AAA was first published by Balko and associates in 1986, the first published human experience was by Parodi in 1991, and the first device manufactured was designed by Harrison M. Lazarus and developed by Endovascular Technologies Company.⁸⁻¹⁰ In September 1999, two devices were granted FDA approval for marketing. Now endovascular repair of AAA offers shorter hospital stays, decreased operative mortality and morbidity and an undisputed advantage to patients with multiple or significant comorbidities. On the other hand, consider the reiterations of multiple laparoscopic dissectors. These instruments have been developed in the attempt to improve laparoscopic dissection, but none with a significant impact on patient outcomes or care.

The impact an innovation has on *technology* can be defined as enabling or refining. An *enabling technology* is an innovation that serves as a platform for further developments within a field. In 1976, the Fischers introduced the modern era of liposuction, which is now one of the most commonly performed cosmetic surgery procedures.¹¹ This innovation has served as a platform for many further developments including ultrasound and power-assisted liposuction. Both ultrasound and power-assisted liposuction represent refining technologies. A *refining technology* is an innovation that marginally improves upon available technology and does not lead to a significant technology change.

Finally, to help describe the *commercial impact* of an innovation, the market-based terms “disruptive technology” and “sustaining technology” are used (Fig. 33.1). A *disruptive technology* is an innovation that supersedes industry leaders and takes over their market share. When disruptive technologies are introduced they are often inferior to the existing leading device and ignored by the incumbent industry leader. In surgery, the device’s inferiority is usually secondary to the device’s learning curve, lack of safety information, and inferior technology. However, as clinicians learn to use the device, as its safety profile expands and as the technology improves, its market share surpasses that of its leading competitor. The

“industry leader” can be applied to the corporation that produces the leading technology, or more broadly the subspecialty that uses the technology. For example, when percutaneous transluminal balloon angioplasty was introduced, its safety profile was not well understood and it was inferior to open coronary artery bypass. Over time, it proved to be a disruptive technology that shifted the market share of patients away from cardiothoracic surgeons (the incumbent industry leaders) to interventional cardiologists. The coronary stent, on the other hand, was a *sustaining technology*. A sustaining technology change is an improvement, usually made by the current industry leader, to maintain growth in the market. The technology can still be enabling (leading to further technology changes) or revolutionary (leading to significant improvements in patient care) but by definition it is not disruptive to market forces. In this case, the coronary stent led to further technologic advancement and improved patient outcomes but did not supersede industrial or clinical leaders. The interventional cardiologist used this technology to maintain their growth in the market.¹

Generally, the larger the perceived benefit of an innovation, the larger the potential for financial return; however, there

Fig. 33.1 Disruptive versus sustaining technology change.

also tends to be more risk involved in all stages of its development. With a revolutionary innovation, there is significant risk in developing the unproven technology, a riskier FDA approval pathway usually requiring pre-market approval, and more resources needed to create a large and experienced development team that can handle the challenges involved in developing a revolutionary technology. A revolutionary innovation, such as the endograft for AAA repair, will also have a large patient impact and large potential market that will justify the increased resources and risk required to develop the device. An incremental innovation, such as the “bullet” endoscopic dissector, has a smaller patient impact and ultimately less potential revenue. To justify its value, there must be less risk and resources involved in its development. Indeed there is less risk in the technologic feasibility of incremental technologies because they generally rely on proven technologies, the FDA regulatory pathway generally falls in a “510(k) pathway”, with faster approval based on predicate devices, and the development team can be a small group of focused individuals. It is important to understand what general category a new innovation falls in so that the risks and subsequently expected benefits can generally be understood.

Funding

An innovative idea develops from concept, to product, to patient use in a stepwise manner. As each milestone is met, the innovation builds value and reduces risk (Fig. 33.2). Funding throughout this process is acquired based on progress towards building value. The initial smaller investment used to prove the innovative concept is termed *seed money*. This smaller investment is generally \$50 000–\$500 000 and can come from a variety of sources: friends and family, angel investors, device company grants, small business innovation research (SBIR) and technology transfer (STTR) grants. Angel investments come from affluent individuals or a group of individuals, often with industry expertise, usually in exchange for ownership equity in the company. Angel investments in

Fig. 33.2 Stages of funding.

2009 were estimated at \$17.6 billion from 259 480 active investors, with a total of 57 225 entrepreneurial ventures receiving angel funding. Healthcare services and medical devices and equipment accounted for 17% of the investments second only to software, which accounted for 19%.¹² By 2013 angel investments had increased to \$24.8 billion with over 298 000 investors compared to \$29.6 billion from venture capital.¹³ Small business technology transfer grants (STTR) reserve a specific percentage of federal R&D funding for partnerships between small businesses and nonprofit research institutions. The idea is to combine the innovative ideas that tend to come out of small businesses or academic centers that lack the means to support serious R&D, with the ability of non-profit research laboratories to develop high-tech innovations. The goal of these partnerships is to transfer the technologies from the laboratory to the marketplace, with small businesses profiting from the commercialization and thus stimulating the US economy. Each year, the Department of Defense, Department of Energy, Department of Health and Human Services, National Aeronautics and Space Administration, and the National Science Foundation are required by STTR to reserve a portion of the R&D funds towards these partnerships.

Larger investments can come from venture or corporate funding. Venture capital funds pool together investments from institutional investors and high net worth individuals. These investors become limited third party investors in the venture fund. The fund then invests in novel technologies that have the potential to generate high commercial returns at the expense of risks too high for the standard capital markets. In exchange for the high risk, venture capital funds buy a significant amount of control and ownership of the company. To ensure realization of the high risk investments, firms look for companies with an innovative technology with the potential for rapid growth with a well-developed business model, impressive management team, and markets valued at greater than \$500 million.

Venture capital is offered in stages, the funding stages parallel the growth of the company. As the new enterprise moves from concept, to company, to product, and finally acquisition, buyout or IPO it gains value and sheds risk. Venture capitalists require a detailed analysis of the development pathway with a focus on reducing risk and building value at critical growth milestones. Examples of critical milestones are securing IP, building a working prototype, successful animal testing, FDA approval and first-in-man use. Paralleling each of these growth milestones are funding benchmarks. The first funding benchmark is the seed stage; as discussed above, this can come from friends and family or angel investors. Many venture capital funds may not invest at the seed stage because the risks are very high and the concept has not been fully realized at this point. The second benchmark is known as start-up stage where the venture is ready to launch; these funds are required for company development, marketing, and product development. The third benchmark, which can be further divided into several rounds, is the expansion stage. Funds here are used for manufacturing, sales, and getting a company to a stage where it starts to turn profits. Often the final financing round is the mezzanine or bridge round which is prior to the final acquisition, buyout, or IPO. In this stage, short-term debt is usually used to support growth opportunities while preparing for an acquisition, a buyout or an IPO.

The first round of external funds is generally called “Series A” and the second round “Series B”. The investment vehicle is generally “Series A Preferred Stock” or “Series B Preferred”. This is preferred equity share in the company, meaning in exchange for their investment, the venture capital (VC) group will have first right to dividends in the case of success and liquidated assets in the case of failure. The equity share in each round is determined by the value of the company at that stage or the “pre-money valuation” in relation to the investment of the VC firm.

Intellectual property

The US Patent and Trademark Office (USPTO) issues several different types of patent documents covering different types of subject matter. Medical devices are most often protected by *utility patents*. Approximately 90% of the patent documents issued by the USPTO in recent years have been utility patents. Utility patents protect any new invention or functional improvements on existing inventions. This can be to a product, machine, a process, a method of making things, or composition of matter. A patent does not grant the *right to use* or sell an invention, rather it grants the *right to exclude* others from making, using, selling, offering for sale, or importing the invention in the United States for up to 20 years from the date of patent application filing. Thus, if an inventor takes a patented laparoscopic grasper and adds a design to make it more ergonomic, and then obtains a new patent on that improvement, he or she can exclude others from using their improvement. However, the new inventor needs the permission of the original laparoscopic grasper to manufacture theirs.

To be considered for patent, an invention must be novel, unobvious, and useful. To be novel, the invention cannot have been known or used by others or even described in a printed publication. Specifically, a US patent cannot be obtained after 1 year from the time an invention has been revealed through public use or publication. In many countries, the 1 year grace period is not granted. Thus, inventors in the academic environment should obtain intellectual property prior to publishing their work and surgeon inventors should likewise obtain intellectual property prior to public use. The invention must also be unobvious to those involved in the relevant field. Finally, it must be useful, in the case of a surgeon innovator, it must meet a patient or surgeon need.

To make sure an invention or idea is novel, the surgeon innovator can search the literature and the USPTO database. One can begin by using keyword searches to find a similar device on any publically available search engines.^{14,15} Once the closest device or invention is found, the existing patent should be intimately explored to understand which aspects of the innovation are protected and which are not.

There are three main parts of a patent: the figures, the written specifications, and the claims. The patent figures or drawings are required of almost all utility patents. The drawings must show every feature of the invention specified in the claims, and are required by the USPTO rules to be in a particular form. The written specifications are a written description of the invention, how to make it, and how to use it. The USPTO states that the specifications should be, “in such full, clear, concise, and exact terms as to enable any person skilled in the art to which it pertains, or with which it is most nearly

connected, to make and use the same, and shall set forth the best mode contemplated by the inventor of carrying out his invention”. Finally, the claims section is used to describe the scope of protection the applicant is requesting. This section is critical and forms the bases for litigation and prosecuting infringement. Here, technical language should be used to really define the embodiments of your innovation that differentiate it from inventions that came before. In patent language, prior inventions are referred to as prior art. The claims section really defines the invention. Most patents contain about 10–20 claims, though there are some patents with only one claim and others with hundreds of claims. There are two types of claims: independent claims and dependent claims. Independent claims stand alone. Dependent claims, on the other hand, refer to another claim on which it depends, and it has to be read in conjunction with that claim to understand the scope of the claim.

A *full utility patent application* includes the figures, written specifications, and claims as detailed above. Legal counsel, specializing in intellectual property, is advisable at this stage, as the surgeon inventor usually does not have the expertise to ensure that the utility patent meets both the inventor’s and the USPTO’s expectations. Since June 8, 1995, the USPTO has offered inventors the option of filing a *provisional patent application* to provide a lower cost (\$110–220) first patent filing in the United States. A provisional patent protects an invention in its early stages. This document describes the inventions with relevant drawings, without making any claims. Once it is submitted, the USPTO files the information but does not review it until a full utility patent application is ready for review. The provisional patent is valid for a year while the inventor perfects the invention and the utility patent application. Patentability is then evaluated as though filed on the earlier provisional application filing date, however the 20-year patent term would be measured from the later nonprovisional application filing date.

While a provisional patent offers documented protection of an invention in its early stages, patents in the United States are theoretically issued to the “*first-to-invent*” as opposed to the “*first-to-file*” approach taken by other countries. It is thus very important to have adequate proof of the date of inventions through a laboratory notebook that is dated, signed, and witnessed on a regular basis. This documentation of an invention can ultimately alter a patent’s recipient. A surgeon inventor should thus carefully document all inventions, once an invention is deemed novel, unobvious, and useful; perform an initial patent search and then file a provisional patent. Beyond the provisional patent, additional counsel should be obtained. At an academic institution this counsel can be obtained through the technology licensing office.

Institutional technology transfer

In 1980, the Bayh–Dole Act enabled small businesses as well as public and nonprofit organizations, including universities, to retain intellectual property developed during the pursuit of federally sponsored research and development. Since then, there has been an explosion of new relationships between universities, industry, and the federal government. Research universities have not only developed increasingly close ties to

Table 33.1 Basic licensing terms

Issue fee	The fee paid to the licensing body for issuance of the license
Exclusivity	A stipulation guaranteeing that no other group may license the technology for the term of the license
Term	The length of a license
Field of use	Granted use of the patent in specific fields, i.e., medical, industrial, educational
Licensed territory	The specific region granted to the licensee
Annual royalty payment	The annual fee for use of the license
Equity	Equity in the licensee company can be granted as part of the payment for a license
Earned royalty	A percentage of the revenues from products that rely on the licensed patent, paid to the licensing body
Sublicensing fee	The fee paid to the licensing body, if the licensee sublicenses

industry, but through licensing and other forms of technology transfer, universities have become an important force in the development of technology which has ultimately contributed significantly to local regional economic development.^{16–19} In the last two decades, institutional prestige for research universities has been increasingly defined in terms of commercial success, in addition to academic sciences.¹⁸

Most universities have created technology-licensing offices (TLO) to manage their patent portfolios. Surgeon innovators should become familiar with the intellectual property (IP) policies of their specific institution. Most universities have an employee contract that claims IP on any invention created with university resources. Under the Bayh–Dole Act, however, universities are also required to share a portion of new technology revenues with the inventor. The surgeon innovator thus generally begins the process of invention with disclosure of the invention to the TLO. The TLO then evaluates the technology and almost invariably chooses to retain the intellectual property. At this point, depending on the competencies and culture of the TLO, an active or passive role is taken to market a technology to industry and potential developers with the initial goal of understanding the invention's true value. Once the technology and its financial potential are understood, again depending on the culture of the TLO, various steps are taken to develop and license the technology. A fair opportunity to license the technology is generally given to the inventor. There is a huge spectrum of licensing agreements and stipulations that can or cannot be included in a licensing agreement. Some general licensing terms are outlined in Table 33.1.

FDA regulatory approval process

In the United States, medical devices are regulated by the Center for Devices and Radiological Health (CDRH), a branch of the FDA. The CDRH is responsible for promoting and protecting the public health by making safe and effective

Table 33.2 Approval pathways

Device classification	FDA regulatory approval process	Examples
Class I	Exemption: subject to general controls	Hand-held surgical instruments
Class II	510(k) pre-market notification: demonstrates equivalency to class I or class II devices with existing 510(k) approval	Suture materials
Class III	Pre-market approval (PMA): extensive data with preclinical studies and human clinical trials	Breast implants

medical devices available in a timely manner. To determine the safety and efficacy of a medical device, the CDRH has developed three main approval pathways: exemption, 510(k) pre-market notification, and pre-market approval application (PMA) (Table 33.2). The approval pathway is determined by the degree of risk associated with the device and the extent to which it poses new safety and efficacy concerns. Devices are also classified according to their perceived risk and the extent of control needed to ensure safety and effectiveness with a 3-tiered system: class I, class II, or class III. Regulatory control increases from class I to class III.

In general, device class loosely correlates with corresponding FDA approval pathways. Most class I devices are exempt from pre-market notification (PMN) or pre-market approval (PMA); most class II devices require pre-market notification 510(k); and most class III devices require pre-market approval. Class I devices are considered the lowest risk devices. They are subject to general controls. General controls are published standards regarding labeling, manufacturing, pre-market surveillance, and reporting. Devices are placed in this class when general controls alone are sufficient to assure safety and efficacy. Examples of class I devices are hand-held surgical instruments. A total of 47% of medical devices fall under this category and 95% of class I devices are exempt from pre-market notification (PMN) and 510(k) FDA approval pathways.²⁰

Class II devices are higher-risk devices. General controls alone are insufficient to provide assurance of safety and effectiveness. There is, however, enough information available to ensure safety and efficacy with special controls including performance standards, design controls, and post-market surveillance. Most medical devices are considered class II devices. Examples of class II devices include: powered wheelchairs, surgical drapes, surgical needles and suture material, and some pregnancy-test kits. A total of 43% of medical devices fall under this category. Approval of most class II devices requires pre-market notification 510(k). There are about 60 generic class II devices that are exempt from pre-market notification, as long as they meet the requirements of General Controls and Special Controls.

Class I and II devices that require more than General and Special Controls require pre-market review by the FDA with PMN or 510(k). Under 510(k), a manufacturer must

demonstrate that a medical device is substantially equivalent in intended use, technology, safety and efficacy to: (1) a class I or II device with existing 510(k) approval or (2) a device marketed prior to the Medical Device Amendments of 1976, giving it “grandfather marketing” status. One can search the FDA’s 510(k) database for devices already on the market or with grandfather marketing status.²¹ Once a PMN is submitted, the FDA has 90 days to respond. If the FDA agrees that the device is “substantially equivalent”, the manufacturer can market the device. The FDA, on the other hand, can require further data or determine the device is not substantially equivalent and re-classify the device as a class III device.

Class III devices pose the highest potential risk. These devices usually sustain or support life, are implanted, or present significant risk of illness or injury. Furthermore, they have a new intended use or technology that is not equivalent to a prior device. Given the potential safety concerns of class III devices, general and special controls alone will not provide enough assurance of safety and effectiveness. Examples include implantable pacemakers and breast implants. A total of 10% of medical devices fall under this category and these devices will usually require pre-market approval (PMA) from the FDA before they can be legally marketed. The PMA application is significantly more involved than the 510(k). Pre-market approval requires extensive data with preclinical studies, human clinical trials, and a full description of the device, including the details of manufacturing and labeling. Once a PMA is submitted, the FDA has 180 days to perform a detailed review. The FDA can grant the PMA, require more data, deny the claim, or accept with the requirement of post-market surveillance. Any substantial change to a PMN or PMA device requires new clearance.

Clinical testing of an unapproved device that poses a significant risk, or approved devices used for a purpose distinct from its approved indication, requires FDA approval in the form of an Investigational Device Exemption (IDE). The IDE application includes information of the device and the proposed study protocol.²² Both IRBs and the FDA can make the determination of whether a device will require an IDE. If an IRB determines that the device’s risk is not significant, FDA notification is not required and the IRB will oversee the trials. If the request for determination is initially submitted to the FDA, the result is binding.²² The applications and approval leading to *first clinical use* are important, because first clinical use is a key milestone for a new device company. In many cases, if a company fails to reach this milestone within a reasonable amount of time, its funding and viability will be threatened. FDA approval to initiate clinical studies in the United States is estimated to take 3–6 months, with review by IRBs adding an additional 3–6 months. Because of this time delay, many companies choose to perform their initial clinical testing outside the United States. When initial clinical testing is performed within the United States, only about one quarter of the trials are performed at academic institutions, largely attributed to bureaucracy associated with IRBs and contract negotiations at large academic institutions.²³

Conflict of interest

There is an obvious conflict of interest when a surgeon also becomes an innovator of surgical devices. The surgeon

innovator serves to benefit from the rewards of both improved patient care and financial gains as the inventor and possible developer of a given innovation. However, to help bring an invention to the bedside, the clinical inventor often becomes integrally involved in designing and developing the innovation, performing the majority of early animal studies, and eventually taking a leadership role and holding an equity position in the company developing the device. These conflicts of interest must be addressed to ensure patient safety.

There is no one comprehensive regulatory process to address all the conflicts of interest present in the process of surgical innovation. However, there are some processes that help assure third party checks and balances in human trials. Studies required for PMA approval are typically large multicenter randomized trials. The study’s sponsor typically must utilize a contract research organization (CRO), core laboratories, a data safety monitoring board (DSMB), and an executive committee, to help resolve potential conflicts of interest. The CRO helps recruit, qualify, and audit sites. Core laboratories evaluate primary data in a blinded manner. The DSMB is composed of a group of senior clinical investigators and statisticians with no other involvement in the study. They review the data at specified intervals with a mandate to stop or modify the study if harm to study participants, including an obvious benefit in one arm of the study, becomes evident. Ultimately, it is incumbent on the surgeon innovator to advance the technology they feel may benefit their patients. To do so, he/she should try to separate themselves, as much as feasible, from activities where financial gain will bias objective analysis. To help identify and avoid conflicts of interest, the surgeon innovator should also provide colleagues and patients with full disclosure of industry relationships.

Innovations in plastic surgery

Innovation in plastic surgery continues to advance our field. There is a large list of recent innovations that spans every field within plastic surgery. The impact of the various new technologies is as diverse as the technologies themselves. Negative pressure wound therapy (NPWT) was a *revolutionary innovation* in its impact in wound care and has proven to be a *disruptive technology* in its commercial impact. Acellular dermal matrix (ACM) is being used in more and more applications within plastic surgery and may become a *disruptive technology* that replaces prior synthetic or living tissue substitutes. Finally, liposuction was an *enabling technology* that served as a platform for further *refining technologies*, including noninvasive body sculpting. This small sampling of recent innovations is discussed below and we briefly touch on the spectrum of their impact on patient care, the market, and further innovation.

Negative pressure wound therapy

In the late 1980s, Drs. Louis Argenta, MD and Michael Morykwas, PhD, both professors of plastic surgery at the University of Wake Forest, developed an innovative approach to the treatment of acute and chronic wounds through the use of sub-atmospheric pressure known today as negative pressure wound therapy (NPWT). In 1993, a partnership between KCI

Fig. 33.3 Global wound care market share, 2013.

Fig. 33.4 Negative pressure wound therapy.

and Wake Forest allowed KCI to commercialize what became KCI's proprietary VAC therapy system. Two years later, the system was approved by the FDA and launched. Then in 2000, KCI received approval for Medicare Part B reimbursement for VAC therapy, making it available to elderly and disabled homecare patients in the United States. This *revolutionary technology* has changed the way many acute and chronic wounds are treated. Today, KCI's wound VAC has served more than 9 million patients worldwide. Its commercial impact continues to be an example of a *disruptive technology*. In 2013, NPWT had the second largest share of the wound care market, second only to traditional adhesive bandages²⁴ (Fig. 33.3), meaning many of the prior industry leaders have been displaced by this new competitor.

NPWT, also referred to as vacuum-assisted wound closure, applies continuous intermittent sub-atmospheric pressure to the surface of a wound (Fig. 33.4). Several potential mechanisms have been proposed to explain how NPWT works. One proposed mechanism is that it reduces wound edema. By removing this transudative and exudative fluid, NPWT improves oxygenation to cells. NPWT also diminishes mediators of the inflammatory response. In humans, it has been shown to decrease matrix metalloproteinase. MMPs inhibit angiogenesis by generating inhibitors such as angiostatin and endostatin.²⁵ NPWT is also thought to act via mechanotransduction; the conversion of mechanical stimulus into chemical activity. *In vitro*, the mechanical deformation increases human fibroblast growth and migration and in animal models of wound closure, the mechanical deformation correlates to increased collagen organization and expression of vascular endothelial growth factor and fibroblast growth factor.^{26,27} These modifications of a wound's microenvironment make it more conducive to wound healing.

NPWT is being used to treat a spectrum of wounds including acute wounds, diabetic wounds, open abdominal and sternal wounds, pressure ulcers, and in conjunction with grafts and flaps. However, high quality evidence supports its use over conventional techniques, most clearly in the setting of diabetic foot wounds. When compared with wet to dry dressing changes in diabetic foot ulcers, NPWT reduces time

to wound closure, length of hospitalization, complication rates, and costs.²⁸⁻³⁵

There is a lack of high level or consistent evidence, however, to support its superiority when compared with traditional moist saline dressings in non-diabetic wounds. In these settings, the more clear advantage was that NPWT met additional surgeon-user needs including decreased number of dressing changes and ease of use. In the traumatic setting, there are observational studies that show its efficacy is comparable, but not superior, to standard dressing changes,³⁶ however the frequently cited advantages, in the trauma population, are: ease of application, decreased number of dressing changes, and reduction in the complexity of subsequent reconstructive surgery.^{37,38} In the treatment of pressure ulcers, no statistically significant differences have been shown in wound surface area, however the cited advantages have been improved patient comfort and less labor intensity.^{39,40}

High-level evidence showing the superiority of NPWT compared with traditional moist saline dressings is still lacking, however it is clear that NPWT meets very specific needs of the surgeon or end user. NPWT is easy to use; it decreases the number of dressing changes for both the patient and the medical caregiver and ultimately prepares the wound for surgical closure by tertiary intention. By understanding and meeting the needs of the surgical community, the plastic surgeon and engineer that developed NPWT changed the armamentarium of the general surgeon's approach to the open abdomen, the cardiothoracic surgeon's approach to post-sternotomy mediastinitis, the vascular surgeon's approach to groin wounds and, ultimately, the plastic surgeon's approach to all of these wounds as well as graft and flap reconstruction. The clinical adoption, despite lack of high level and consistent data, makes it a *revolutionary technology* that translates into a commercially *disruptive technology* (see Fig. 33.3).

Acellular dermal matrix

In recent years, acellular dermal matrix (ADM) is emerging as a *disruptive technology* in both reconstructive and aesthetic

Fig. 33.5 Acellular dermal matrix.

surgery. ADM is a dermal graft in which the dermis is separated from the epidermis and all cellular elements, to avoid tissue rejection and graft failure (Fig. 33.5). The dermal matrix then acts as a scaffold that permits tissue regeneration with revascularization and repopulation with fibroblasts. The ADM is thought to incorporate into surrounding tissue and eventually be replaced with host collagen.⁴¹

Its use has been described in the burn literature for over 20 years; initially as a substitute, and now as a complement to skin grafting. In the field of breast surgery, ADM was first described in revision aesthetic cases to address rippling and symmastia.^{42,43} In 2005 it was introduced in reconstructive breast surgery as a tool for direct-to-implant reconstructions.⁴⁴ In 2007 its use in two-stage breast reconstruction with a tissue expander was described.⁴⁵ ADM is used to provide additional coverage of implant-based reconstructions, support for faster inferior pole expansion, as well as assistance with precise placement of the inframammary fold.^{46,47} Overall, studies still conflict on its risk profile for postoperative breast complications. A retrospective analysis of 415 immediate implant-based breast reconstructions showed that ADM is associated with high rates of postoperative seromas and infection.⁴⁸ ADMs, however, are used in over 60% of implant-based breast reconstructions. In this market ADM has disrupted the prior

ADM: a disruptive innovation in implant-based breast reconstruction

Fig. 33.6 ADM is emerging as a disruptive innovation in implant-based breast reconstruction.

“leader” which was implant-based reconstruction with partial or total muscle coverage (Fig. 33.6). Similar to NPWT, ADM has been adopted prior to data to support its superiority to traditional methods. Its adoption may be attributed to ease of use and meeting surgeon needs that include a quick way to reconstruct the inframammary fold.

ADM is also largely replacing the use of synthetic meshes in contaminated abdominal wall defects. These bioprostheses are thought to incorporate into contaminated tissue without becoming infected.⁴⁹ This is an important competitive advantage when compared to synthetic mesh, which is contraindicated in this setting. There still remains a question of the longevity of mechanical integrity ADM provides in abdominal wall reconstruction. However, because ADM has met the need for a large fascial substitute that can be used in the setting of a contaminated wound, many plastic surgeons quickly adopted this new technology, despite these unanswered questions. Interestingly, by embracing ADM-based abdominal wall reconstruction, plastic surgeons are expanding their role among general surgeons in this arena.

Like other disruptive technologies, this emerging technology lacks long-term follow-up, familiarity, and a complete safety profile. However, it is a soft-tissue substitute that needs not be harvested, thus fills a principle need of the reconstructive surgeon. This technology may thus go on to expand its indications, supersede other synthetic technologies, and replace more invasive reconstructive options of the present.

Noninvasive body contouring

The push towards noninvasive medical interventions is an important force driving the patient-consumer market for medical intervention. At its inception over three decades ago, liposuction itself was a large step in a less invasive form of body contouring compared with traditional surgical approaches. The introduction of liposuction, like other *enabling technologies*, served as a platform for the continued introduction of *refining innovations*. The Fischers first introduced sharp suction techniques for fat removal in 1974. Illouz then refined the technique with the introduction of high power negative pressure suction connected to blunt tip cannulas as well as the

development of the “wet technique” used for hydrodissection to assist with fat removal.⁵⁰ In the 1980s, Dr. Jeffrey Klein introduced the tumescent technique that had an important impact on the safety and efficacy of liposuction. The high volumes of diluted lidocaine and epinephrine decreased the need for general anesthesia and minimized blood loss.⁵¹

To address surgeon fatigue and improve effectiveness, especially in more fibrous areas, several *refining innovations* have been introduced, none of which have made a significant change in this field.⁵² Ultrasound-assisted liposuction (UAL) was developed by Zocchi in the 1980s. Ultrasonic waves were introduced to rupture adipocytes creating microcavitations of liquefied fat. Controversy exists as to whether UAL reduces complications or improves efficacy when compared with traditional techniques.^{53,54} Similarly, power and laser-assisted lipolysis were refinements to traditional liposuction that have not shown significant differences in clinical outcomes.⁵² Focused ultrasound body contouring is a recent innovation that introduces a potentially new frontier in body contouring that may or may not prove to be efficacious. This technology uses focused ultrasound energy delivered through a handheld probe (Fig. 33.7). The ultrasonic waves are focused in the subcutaneous fat, causing permanent disruption of fat cells with the aim of not damaging the epidermis, dermis, or underlying tissues and organs. The disrupted adipocytes are then supposed to be metabolized by the liver. The procedure is a change from prior refinements, as it requires no incisions or injections. This technology is not FDA approved for use in the United States. Small preliminary clinical trials and use outside of the United States have demonstrated safe and effective treatment in small areas.^{55–57} Since its inception in the 1970s, liposuction has proven to be an enabling technology that continues to serve as a platform for numerous refining technologies.

Robotics in plastic surgery

Amir E. Ibrahim, Karim A. Sarhane, and Jesse C. Selber

 Access video content for this chapter online at expertconsult.com

SYNOPSIS

- This chapter details the recent history of innovations in robotic plastic surgery. Clinical applications are described and discussed. Future perspectives for the growth and dissemination of this field are outlined.
- Robotic technology is the next step in the evolution of minimally invasive techniques, adding enhanced precision and visualization, augmenting the capabilities of plastic surgeons, and aiding in achieving more precise interventions.
- The robotic interface has provided the necessary exposure and picture clarity through high-resolution, three-dimensional optics and the precision instrumentation to accomplish minimally invasive muscle harvest, including microvascular pedicle dissection, without additional skin incisions.
- With improved visualization, elimination of physiologic tremor, motion scaling, and decreased fatigue, the surgical robot has emerged as a potentially useful tool in microvascular, microlymphatic and microneural surgery.
- Trans-oral robotic surgery (TORS) has been shown to be a reasonable alternative to chemoradiation treatment for many tumors of the hypopharynx. Reconstructive techniques using the robot to access oropharyngeal anatomy has allowed more of these defects to be reconstructed without splitting the mandible and thus have extended the indications for TORS.
- The intrinsic features of robots, including superhuman precision, high definition, three-dimensional optics and minimally invasive capabilities, have enabled plastic surgeons to perform minimally invasive approaches to procedures never before possible.
- The application of the robotic platform to microsurgery is growing owing to the development of new microsurgery-specific robotic instrumentation. As more microsurgeons use the robotic platform, an increasing number of manufacturers will be driven to design improved tools for microsurgical procedures.

Introduction

The word “robot” was first introduced to the English language and to science fiction in 1921 by Karel Čapek in his play

Rossum’s Universal Robots; it is a term derived from the Czech word *robota*, which means “forced labor”.¹ Since then, robots have assumed an increasingly significant role in both industry and medicine. It was the National Aeronautics and Space Administration (NASA) and the US Army who initially promoted the concept of robotics in surgery after their development of telepresence surgery (operating remotely) for use in wartime and for space applications.¹

The history of robotic surgery began with Puma 560 which was first used by the neurosurgeon Kwoh to achieve improved absolute positioning accuracy for CT-guided stereotactic brain surgery.² Three years later, Puma 560 was used by the urologist Davies to perform a transurethral resection of the prostate.³ This platform led to the development of the PROBOT, a robotic system specifically designed for transurethral resection of the prostate.⁴ At the same time, orthopedic surgeons were also taking advantage of robots’ greater precision; they developed a system that could assist in total hip arthroplasty (preparing the human femur for artificial hip replacement).⁵ The RoboDoc system (Integrated Surgical Systems, Inc., Sacramento, CA) was eventually developed and used to prepare the femoral canal for prosthesis placement; RoboDoc was the first surgical robot approved by the FDA.⁶

Based on the promise of surgical robotics, several other systems have been researched, and then commercially developed and approved by the FDA to integrate various fields. These included the Automated Endoscopic System for Optimal Positioning (AESOP) system (Computer Motion Inc., Santa Barbara, CA), a voice-activated robotic endoscope, and the comprehensive surgical robotic systems, Zeus (Computer Motion Inc., Santa Barbara, CA) followed by da Vinci (Intuitive Surgical Inc., Mountain View, CA).⁷

The da Vinci platform is a so-called “master-slave” system, meaning that robotic arms are controlled remotely from a console in which the surgeon sits and performs the surgery. The da Vinci system is composed of three components: a vision tower that holds a dual light source and dual 3-chip cameras, a master console where the operating surgeon sits,

Fig. 34.1 The full da Vinci Si HD surgical system (from right to left): an imaging cart, a mobile cart with four articulated arms, and a console for the surgeon to control the robot arm (reprinted with permission from Intuitive Surgical, Sunnyvale, CA).

and a moveable, patient-side cart, where two instrument arms and the camera arm are mounted⁸ (Fig. 34.1).

Robots have been used in a variety of minimally invasive surgeries, including cholecystectomies, mitral valve repairs, radical prostatectomies, reversal of tubal ligations, in addition to many gastrointestinal surgeries, nephrectomies, and kidney transplants.⁷ Advantages are many as robots were able to overcome the shortcomings of laparoscopy, and have made possible surgeries that were previously technically unfeasible. These benefits include increased dexterity, improved visualization, restoration of proper hand–eye coordination, elimination of physiologic tremors, ability to scale motions, seven degrees of freedom, and an ergonomic surgeon positioning.⁹

Robotics in plastic surgery

Inspired by the success of robotics in these other surgical specialties, the senior author (JCS) began investigating the use of robots in plastic surgery in 2003. Over the subsequent 10 years, three applications of robotics in plastic surgery were developed: (1) trans-oral robotic *reconstructive* surgery (TORRS) for head and neck reconstruction, allowing complex oropharyngeal reconstruction without dividing the lip or mandible; (2) robotic microvascular, microneural, and microlymphatic anastomoses, extending the capabilities of the human hand to “supra-human” precision; and (3) minimal access muscle harvest for an “incisionless” harvest of both the latissimus dorsi and rectus abdominis muscles. In this chapter, we present the clinical experience of robotic surgery in those areas.

Trans-oral robotic *reconstructive* surgery (TORRS) (Video 34.3 ►)

Malignant lesions of the oropharynx and base of tongue remain a prevalent and challenging entity to treat. The frequent need for debilitating surgical procedures (lip and mandible splitting) to resect such tumors has led to the use of primary chemoradiation therapy as an alternative treatment.^{10,11} However, toxicity rates following such approach were considerably high and functional status was not improved.¹² The advent of robotic surgery for minimally

invasive resection of oropharyngeal malignancies has witnessed the return of surgery as a primary treatment modality for such tumors.^{13,14} Trans-oral robotic surgery (TORS) offered the possibility of achieving loco-regional tumor control while avoiding the need for mandibulotomies and chemoradiotherapy, optimizing both oncologic and functional outcomes. The reconstructive challenge created by these minimally invasive resections is that the cylinder of the oropharynx remains almost entirely closed, severely restricting its access when attempting to inset and contour vascularized tissue. The anatomic region between the uvula and the epiglottis is particularly difficult to approach without a mandibulotomy or a wide pharyngotomy. Trans-oral robotic *reconstructive* surgery (TORRS),¹⁵ whether using free flaps, local flaps, or primary closure, allows access to this difficult anatomy to facilitate suture approximation and achieve the goals of reconstruction: preservation of a competent velopharyngeal sphincter, a watertight seal between the pharynx and neck, adequate sensation and volume in the tongue base, and optimization of the physiological function of the oropharynx and larynx.^{16,17} Set-up involves positioning the patient-side cart at about 60° from the head of the bed. A mouth retractor is used to establish the interdental opening and the endoscope and two instrument arms are passed into the mouth, converging to the target anatomy (Fig. 34.2).

The “remote center” of the instruments is the virtual, three-dimensional point around which the instruments’ pivot is placed at the level of the mouth opening to minimize movement around the teeth. Complex manipulation of tissue, including delicate suturing, can then be performed. This approach appears to be a superior option in select cases, and also holds promise in expanding the indications for minimally invasive reconstructive procedures. Combining trans-oral robotic flap inset with manual inset through the pharyngotomy defect is also possible. In these cases, however, it is important to note that a pharyngotomy is considerably smaller than the wide pharyngotomy traditionally required for accessing such tumors, since access to the upper pharynx is achieved robotically rather than through the neck. The senior author has documented the value of TORRS for challenging defects of the head and neck, and has shown both the feasibility¹⁸ and effectiveness¹⁹ of this reconstructive method. In addition, by taking this approach, plastic surgeons are able to provide a

Fig. 34.2 Trans-oral robotic reconstruction requires a mouth retractor to set the interdental opening. The robotic endoscope and two robotic instrument arms are introduced through the mouth and converge on the target oropharyngeal anatomy. External view (A) and depiction of internal view (B) is shown. (From Selber JC, Sarhane KA, Ibrahim AE, Holsinger FC. Transoral robotic reconstructive surgery. *Semin Plast Surg.* 2014;28:35–38.)

reliable reconstructive support for the head and neck surgeon to robotically resect larger, deeper, and more complex tumors that would be very challenging to reconstruct through traditional methods.

Indications for TORRS application are still not completely defined. Longfield *et al.* recently proposed an algorithm for the use of TORRS based on tumor site, tumor extent, and patient-specific factors.²⁰

Robotic microsurgery (Video 34.1 ►)

One of the most promising applications of robots in plastic surgery is microsurgery. With complete tremor elimination and up to 5:1 motion scaling, the surgical robot is capable of superhuman levels of precision. In no area is this precision more important than in microsurgery. Furthermore, with its high-definition three-dimensional optics and up to 10× magnification, robots provide a nearly ideal platform for performing delicate microvascular manipulations. Robotic microsurgery was first investigated in a rat model where it showed a significantly slower time to anastomosis versus conventional microsurgery, with no difference in technical failures or patency rates.²¹ A more recent objective study compared 30 standard and 31 robot-assisted anastomoses, and showed excellent patency rates for both methods, but a significantly longer time for robotic cases.²² In contrast, Katz *et al.* showed a learning curve that resulted in a decrease of

robotic anastomotic time from 67 to 20 minutes.²³ Morita *et al.* reported a quantitative assessment of robotic versus freehand tasks in a microsurgical setting; a simulated deep and superficial surgical field was created and robot assistance was more successful for the deep microvascular tasks.²⁴

In the senior author's initial series of trans-oral robotic reconstruction of oropharyngeal defects,¹⁹ the robot was used to perform the microvascular anastomoses. The facial artery, which is the most common recipient artery, is found passing beneath the hypoglossal nerve and digastric sling, often high under the body of the mandible. If a tracheostomy and ventilator tubing is also connected, the space available to perform the anastomosis may be limited. The robot's precision and visualization in confined spaces makes it well suited for anastomoses in such cases. Similarly, Song *et al.*¹⁷ used the robot for microvascular anastomosis of a radial forearm flap (recipient vessel: facial artery) to reconstruct the defect created by resecting a tonsillar tumor (T3 N0 M0, stage III); the neck dissection was performed through a retro-auricular incision. In this type of approach, the authors also stated it is more difficult to perform the micro-anastomosis through the narrow space using a conventional microscope. Set-up for robotic microsurgery is relatively straightforward. The robotic arms are placed at about 45° above the target anatomy and in direct proximity to the external incision (Fig. 34.3) (Video 34.5 ►).

A third arm with a “fine tissue forceps” attachment serves as a stationary assistant, and the surgeon is able to toggle back

Fig. 34.3 Robotic lymphovenous bypass. The robotic camera is positioned in the middle, and the two arms are on either side of the forearm (A). Lymphovenous bypass completed (B).

and forth between arms 1 and 3, depending on which arm is being used to position the vessel, and which is being used to suture. Black Diamond Micro Needle drivers (Intuitive Surgical) replace the larger jawed needle drivers used during the inset, and a 9-0 nylon suture is used for the anastomosis.

The main highlights of robot-assisted surgery (ultra-precision and 100% tremor filtration) are currently being expanded to the field of super-microsurgery, specifically to lymphedema surgery. Lymphaticovenular bypasses are generally performed end-to-end using 11-0 or 12-0 nylon sutures on a 50- μ m needle.²⁵ These are extremely technically challenging cases, and in certain cases exceed the limits of human precision. The supra-human precision afforded by the robot can be of great benefit in this setting. The senior author has performed several lymphovenous bypass surgeries using the da Vinci platform and found it to be promising for this application. In addition, the robotic platform allows rapid transitioning of the visual system between near-infrared laser visions (when using indocyanin green to identify lymphatics) to normal bright field vision, which is a great advantage for lymphatics surgery when identifying lymphatic vessels using physiologic flow.

The advantages of robotics over endoscopy (disappearance of physiological tremor, three-dimensional vision, high definition, magnification, and superior ergonomics) have led to its use for microneural and brachial plexus surgery. Nectoux *et al.*²⁶ demonstrated the feasibility of robotic microneural repair in their experiments on fresh nerves (rat thigh sciatic nerve, pig upper limb median nerve, and human wrist median nerve, human wrist ulnar nerve, and human finger collateral nerve) using either an anatomical (epiperineural repair) or a neurotrophic technique (nerve regrowth guide). Repairs were all performed without any damaging movements. They concluded that the robot allows very safe and precise peripheral nerve repairs by counteracting physiological tremor and improving the overview of the surgical field.

These promising results allowed them to use the robot for intraneural dissection of peripheral nerve tumors.²⁷ The robotic approach permitted, in addition to a minimally invasive approach, a higher degree of precision, allowing identification of the fascicles with greater accuracy and safety.

The brachial plexus is composed of a complex web-like array of nerves and several intertwined connections, making it a very intricate anatomical environment which poses great surgical challenges. Access to the brachial plexus traditionally requires a long incision, with significant dissection, and this often results in substantial scarring and adhesions. For this reason, the traditional approach has been to treat closed injuries with watchful waiting. However, this can lead to a delay in exploration of 3 to 6 months post-injury. Although endoscopic approaches could mitigate the cost of early exploration by reducing incisional morbidity, the technique does not allow finely tuned microneural repairs. A minimally invasive approach with three-dimensional (3D) high-definition, high-magnification vision allows early exploration of the brachial plexus to diagnose the injuries and perform higher quality microneural repairs without the open incision. Facca *et al.*²⁸ have presented their experimental and clinical experience in robotic-assisted surgery of the shoulder girdle and brachial plexus. In their cadaveric studies, they were able to dissect the supraclavicular brachial plexus and adjacent anatomical structures (jugular vein, omohyoid

muscle, phrenic nerve, scalene muscles, and nerve roots from C4 to C7). A complete dissection and full exposure of the supraclavicular portion of the brachial plexus was successfully achieved. They were also able to graft a nerve segment into an artificially created gap by performing separate epi- and perineural repairs with 10-0 nylon.

Finally, it is worth noting that new directions for robotic microsurgical applications are being explored in the field of urology. These include robotic-assisted vasectomy reversal, sub-inguinal varicocelelectomy, denervation of the spermatic cord, and testicular artery re-anastomosis (in case iatrogenic injuries occur). Parekattil *et al.*²⁹ presented their experience with these techniques and concluded that the use of robotic assistance in microsurgical vasovasostomy may have benefit over conventional techniques in decreasing operative duration and significantly improving early semen analysis measures. As for robotic-assisted microsurgical subinguinal varicocelelectomy, this technique appears to be feasible, and there are potential advantages in decreasing operative duration and improving surgeon efficiency.

Robotic microvascular anastomosis is a burgeoning application whose future in microsurgery is promising. Preliminary results suggest that surgical robots could play a key role in microsurgery in the future.^{28,30-32} The current limitations of the robotic platform for microsurgery include inferior optics of the endoscope compared to the operating microscope, instruments that are clumsy compared to fine microsurgical instrumentation, and lack of haptic (sensory) feedback. Only one study has objectively assessed haptics and concluded it was not crucial to completing an accurately tied knot with a microsurgical suture.³³ Subjects tied knots and tightened them with eyes open and closed with robotic assistance. No difference in suture breakage and poor tightening was observed.³³ The senior author's experience is that microsurgery is 90% visual, and most of what we imagine we are feeling, we are actually seeing, and our brain is supplying the illusion of sensation. The 10% of haptic feedback that is real, however, is a very important component and, at this time, constitutes a barrier to robotics playing a more active role in microsurgery. In addition, the robotic endoscope is limited in both its clarity, resolution and magnification compared to the optics of more traditional operating microscopes. These differences can be overcome with better quality, fixed distance lenses fitted to the stereoscopic optical system of the robot. More delicate instruments are required which bear greater resemblance to traditional microsurgical instruments and would accommodate basic forms of haptic feedback (see below).

Robotic muscle harvest: latissimus dorsi and rectus abdominis (Videos 34.2 and 34.4)

Free and pedicled muscle flaps have been in use by plastic surgeons for a variety of applications since World War I, and remain work horses in scalp, extremity, head and neck, and breast reconstruction. Harvest of muscle flaps traditionally requires incisions that provide access to muscle origin, insertion and pedicle ranging from 20 to 40 cm in length. These donor sites are conspicuously located on the abdomen and back, and are a source of morbidity in the form of poor cosmesis, discomfort, seroma and hernia. Because of the desirability for minimally invasive harvest, endoscopic and laparoscopic techniques have been attempted, but have not

achieved broad acceptance due to technical challenges related to exposure, retraction and lack of appropriately precise instrumentation.^{34–36} The robotic interface has supplied the necessary exposure and picture clarity through high-resolution, three-dimensional optics, and the necessary precision instrumentation to accomplish both muscle and pedicle dissection. For this reason, robotic muscle harvest holds excellent promise in reducing donor-site morbidity for these common reconstructive procedures. The senior author has designed and refined the technique to harvest both the latissimus dorsi and rectus abdominis muscles.

Robotic harvest of the latissimus dorsi muscle flap was developed in a cadaver model in 2010.³⁷ It was first used clinically in 2011 in a series of 8 patients,³⁸ and has since been used in over 40 latissimus harvests at the senior author's institution. It is a safe procedure with diminished donor-site morbidity and no major complications. The approach involves a short axillary incision, or simply use of the existing mastectomy incision or sentinel lymph node incision, two additional ports, and insufflation. The entire muscle can be harvested and transposed through the small incision, and has many uses as a free and pedicled flap, including partial breast reconstruction and implant coverage, as well as free flap applications. Over the past two years, this harvest technique has been gaining popularity among breast reconstruction surgeons as it proved to be a feasible technique that allows adequate coverage of the breast providing a reliable reconstruction with hidden incisions. The technique has been performed worldwide. Its major indications include reconstruction of lateral defects following partial mastectomy, implant-based reconstruction following nipple–areola complex sparing mastectomies, and in secondary reconstruction in patients with expanders who received adjuvant radiotherapy (delayed-immediate protocol). Additionally, it can be used for chest wall deformity correction in patients with Poland syndrome.³⁹ The operative procedure is discussed in detail elsewhere.⁴⁰ A novel gasless technique using an articulated long retractor to maintain an adequate working space and enable latissimus dorsi muscle dissection (without gas insufflation) was also recently described.³⁹ In addition to improved cosmesis, the robotic approach demonstrates reduced patient discomfort, decreased seroma formation and shortened length of stay compared to the open procedure (Fig. 34.4).

Robotic harvest of the rectus abdominis muscle uses an intraperitoneal approach, avoiding violation of the anterior rectus sheath and hence decreasing the incidence of postoperative surgical site occurrences.⁴¹ The first published report of robotic rectus harvest was performed on a 30-year-old woman for a lower extremity defect.⁴² The authors observed advantages of the robotic approach, including uninhibited 3D view of the rectus muscle and the deep inferior epigastric artery (DIEA), dexterity levels similar to human hands, and a clearer image than traditional laparoscopy. Additionally, during the dissection it was noted that gravity serves to auto-retract the muscle and makes the perforators and inscriptions easier to visualize. The operative procedure is discussed in detail elsewhere.⁴³ Based on our experience, robotic harvest of the rectus muscle is a valuable option for plastic surgeons, and can be performed for many different types of reconstructions. Indications are classified according to the pedicle supplying the flap. A superiorly-based pedicled flap is used for the coverage of anterior midline chest wall and sternal defects following

oncologic resection or wound debridement. Inferiorly based flaps are used to reconstruct abdominopelvic defects where either space obliteration or visceral protection is needed: abdominoperineal resection, radical cysto-prostatectomy, pelvic exenteration, and coverage of major vessels or visceral repairs. Harvest of the muscle for free tissue transfer can also be performed robotically, and indications are primarily scalp and extremity, as in the traditional approach. We observed several key advantages associated with the robotic approach for this surgery. As outlined above, the rectus muscle is traditionally accessed through long incisions to free its origin and insertion. With the assistance of the robot, these are reduced to ports, with less risk of wound complications and improved cosmesis. Maintaining the integrity of the anterior rectus sheath resulted in a minimal incidence of hernias and bulges. Overall, less tissue violation is required, and this has resulted anecdotally in markedly reduced postoperative pain and patient discomfort, shorter length of hospital stay, and more rapid functional recovery. Finally, this procedure can easily be combined with other pelvic procedures. This is of great value to a complex, multi-disciplinary robotic surgery program where large resections are being performed without a laparotomy (Fig. 34.5).

In sum, robotic muscle harvest techniques are safe and effective, and have a place in the practice of reconstructive surgery.

Limitations of robotic surgery

Cost

Cost presents the commonly discussed obstacle to routine use of the robot in plastic surgery. The current cost of the da Vinci system is \$2.2 million and annual maintenance is \$138 000. This cost has been accepted by hospitals in anticipation of increases in patient volume and reputational benefit. The determinate of whether a robotic practice is profitable is the *contribution margin per case*. This is calculated by subtracting the cost per case from the revenue per case. For most cases, revenue from a robotic case is the same as the open procedure, fixed by the professional fee charged by the doctor and the hospital fees, based on the DRG (there are no special robotic surgical codes). For robotic procedures, OR cost may be higher due to instrumentation, staffing levels and OR time, particularly if the procedure takes longer when done robotically. On the other hand, hospital costs may decrease if minimally invasive robotic procedures are associated with shorter lengths of stay and lower complication rates. The balance of revenue and cost per procedure will determine if the robotic procedure is cost effective. In our institution (MD Anderson Cancer Center), a robotic latissimus dorsi (LD) harvest costs an additional \$800 to \$900 as compared to an open LD flap.⁴⁴ Although at first glance cost seems to be a substantial drawback for the widespread application of the robot, when considering the advantages offered in terms of decreased morbidity and hospital length of stay, robotic-assisted procedures might compare favorably to traditional approaches.⁴⁴ Prospective long-term studies are needed to objectively assess the cost-effectiveness of this new technology in terms of operative time, recovery period, hospital length of stay, and morbidity rates.

Fig. 34.4 (A) Markings and port placement. The borders of the latissimus dorsi muscle are marked according to anatomic landmarks. An axillary incision is then marked. For breast reconstruction, the sentinel lymph node incision is used. If a free flap is planned, then an incision is made that will facilitate pedicle dissection, dissection of the subcutaneous space anterior to the muscle, and placement of a port at the inferior end. Two additional ports are marked 8 cm from the end of the axillary incision and anterior to the muscle and 8 cm distal to the second port and anterior to the muscle. (B) After port placement, the robotic side cart is positioned posterior to the patient with the two robotic arms and the endoscope extending over the patient in proximity to the ports. (C) Transposition of latissimus dorsi muscle underneath a subcutaneous skin bridge. (D) Latissimus dorsi muscle achieves total muscle coverage over a permanent silicone shaped implant. (E) 90-cm² scalp defect from resection of a squamous cell carcinoma. (F) Three weeks postoperatively, his scalp is well healed, and he is marked for radiation simulation. (G–H) Case of immediate breast reconstruction following a right nipple–areola complex-sparing mastectomy. Besides a very minor contour defect, there is little appreciable difference in the appearance of the donor site before (G) and after (H) surgery. (A,B,E,F from Selber JC, Baumann DP, Holsinger FC. Robotic latissimus dorsi muscle harvest: a case series. *Plast Reconstr Surg.* 2012;129:1305–1312. C,D,G,H from Clemens MW, Kronowitz S, Selber JC. Robotic-assisted latissimus dorsi harvest in delayed-immediate breast reconstruction. *Semin Plast Surg.* 2014;28:20–25.)

Robotic training in plastic surgery

Another important question affecting broader application of robotic-assisted surgery is learning curve. When operating the robot, a comprehensive understanding of its mechanics,

kinetics, and operative dynamics is a major prerequisite; basic functionality alone is not enough. Therefore, a significant amount of time and energy should be spent on learning the subtle nuances of the robotic mechanics to be able to troubleshoot the machine when it is not performing optimally.

Fig. 34.5 (A) Markings and port placement. The contralateral costal margin and iliac crest are marked along a line connecting the anterior axillary line and the anterior superior iliac spine. The midpoint between these two landmarks and 2 cm lateral to it is the desired location of the 12-mm camera port. On either side of the camera port is the planned location of the two 8-mm instrument ports. (B) All three ports are in place and the robot is ready to be docked. (C) Docking the robot. The surgical robot is brought into position perpendicular to the patient on the ipsilateral side to the muscle being harvested. (D) The dual-console system. Instruments can be passed from one surgeon to the other for teaching purposes and the teacher can “telestrate” on the screen so the learner can be guided. (E) After having an exposed and infected arthroplasty endoprosthesis, this patient received a robotically harvested rectus muscle to cover the prosthesis. (F) The donor site. The scars are three small incisions on the contralateral side to the muscle being harvested. (G) After having an exposed medial ankle, this patient also received a robotically harvested rectus muscle flap. (H) The donor site is limited to the three ports because the muscle can be removed through one of the ports using a gallbladder bag. (A–F from Pedersen J, Song DH, Selber JC. *Robotic, intraperitoneal harvest of the rectus abdominis muscle. Plast Reconstr Surg.* 2014;134:1057–1063. G,H from Ibrahim AE, Sarhane KA, Pederson JC, Selber JC. *Robotic harvest of the rectus abdominis muscle: principles and clinical applications. Semin Plast Surg.* 2014;28:26–31.)

Appropriate teaching modules and evaluation and credentialing systems for specific plastic surgical skill sets do not yet exist despite much technological advancement. Surgical training curricula have stayed more or less the same for more than a century. Residents and fellows have always learned surgery through “supervised trial and error” on patients. This method makes training completely dependent on the case load; it may even prolong surgical training in some cases. Such an approach cannot be extended to robotics as current caseloads are very limited; this makes the learning curve for robotic surgery very

long. In this regard, simulation centers might be a better medium for acquisition of robotic surgical skills. In such settings, trainees can use surgical robots to practice operations on three-dimensional, virtual-reality visual simulations and soft-tissue models that recreate the textures of human tissues through force feedback (haptics).^{45,46} Furthermore, trainees can be supervised through tele-mentoring. This approach has the potential to considerably improve the learning curve of robotic surgery, allowing trainees to acquire robotic skills in a relatively shorter period while minimizing surgical errors and

thus enhancing patient safety. We must work as a specialty to define competency in robotic plastic surgery to insure it is being done safely and according to best practices.

For robotic microsurgery training, considering its technical complexity and the consequences of its failure, advanced teaching modules and robust learning assessment tools are needed to ensure a solid training and safe use. Unlike many other robotic versions of open procedures, robotic microsurgery combines the same principles as conventional microsurgery (for which a number of training modules already exist)^{47,48} with an additional skill set unique to the surgical robot. To better assess trainees and evaluate this mixture of skills, the senior author created the Structured Assessment of Robotic Microsurgery Skills. This evaluation system combines the Structured Assessment of Microsurgical Skills scoring system with other validated skill domains pertaining specifically to robotic surgery.⁴⁹ The Structured Assessment of Robotic Microsurgical Skills includes three parameters to assess conventional microsurgical skills, including: (1) dexterity, (2) visuospatial ability, and (3) operative flow. The robotic skills incorporate five additional parameters, including: (1) camera movement, (2) depth perception, (3) wrist articulation, (4) atraumatic tissue handling, and (5) atraumatic needle handling. Each parameter is scored from 1 to 5, with 1 being the worst and 5 the best. The overall performance and overall skill level are also assessed independently.^{50,51} We have recently used this new robotic microsurgical evaluation system to plot the maturation process of these skills in a heterogeneous cohort of surgeons including clinical fellows, research fellows, and experienced microsurgeons. In this study, we successfully validated this new assessment instrument with excellent consistency and high levels of interrater reliability. We were further able to demonstrate improvement in robotic microsurgical skill across our heterogeneous group of learners. All skill areas and overall performance improved significantly for each participant over the five robotic microsurgery sessions. Operative time decreased over the study for all participants. The results showed an initial steep technical skill acquisition followed by more gradual improvement, and a steady decrease in operative times that ranged between 1.2 hours and 9 minutes. We found that prior experience with conventional microsurgery did in certain areas improve the acquisition of technical proficiency using the robotic system. All groups demonstrated an ability to gain proficiency in robotic microsurgical anastomosis with minimal robot-specific training, indicating that the technical aspects of robotic microsurgery can be gained by learners with no prior microsurgery or robotic experience.⁵² In our prior study of conventional microsurgical assessment data using the Structured Assessment of Microsurgical Skills,⁵³ moderately experienced subjects improved in skill through the middle and upper range of scores.^{53–55} By contrast, in the current study, subjects with no prior experience in robotic microsurgery moved through all but the highest level of Structured Assessment of Robotic Microsurgical Skills scores to achieve proficiency.^{54–57} Because of the inherent benefit of the robotic surgical platform for microsurgery, there is considerable interest in defining its role. To do this in an organized, controlled, and systematic fashion, we have developed a well-defined anastomotic model, a validated assessment tool, and a general sense of the trajectory of learning. These steps are the first on the road to customized education, curricular design with

individual assessment, targeted feedback, and competency-based learning.

New frontiers in robotic plastic surgery

The specific disadvantages of the robotic platform include: (1) lack of haptic feedback, (2) inferior optics as compared to the operating microscope and (3) instrumentation which is poorly adapted to microsurgery. All of these, however, are platform-specific (and not inherent to the field), and thus can be potentially overcome with incrementally improved technology.

A new “six degrees of freedom” test platform, the μ Haptic device, with microsurgical tele-robotics and simulation, was designed and built by a research group in Stanford (although still not formally tested in an animal model to date).⁵⁸ In addition, a new robotic platform that is expected to be available soon (ALF-X multi-port robotic system) will be equipped with platform-exclusive features, such as haptic feedback, possibly enabling endoscopic super-microsurgery.⁵⁹

As for the optics, the telescope-based high-definition video system (VITOM, Karl Storz, Tuttlingen, Germany) which offers 16–18 $\times$ optical magnification (comparable to the operating microscope) has been recently integrated into the robotic TilePro system (Intuitive Surgical Inc.) to provide the microsurgeon with a cockpit view of all video inputs; it can be positioned on an additional fifth robotic (nitrogen-powered, Karl Storz) arm (Fig. 34.6). It has been used so far for robot-assisted vasovasostomy (RAVV) and vasoepididymostomy (RAVE), with improvement in operative time and comparable results to those of traditional microscopic reversal.⁶⁰ Parekattil's group is also involved in clinical trials of a 100 $\times$ digital camera (Digital Inc, China) that can be utilized via the TilePro daVinci S or Si robotic system (Intuitive Surgical, Sunnyvale, CA) to allow the surgeon to toggle or use simultaneous 100 $\times$ and 10–15 $\times$ visualization.²⁹ This has the

Fig. 34.6 Operative set-up for the robotic platform with the additional VITOM lens camera system and point setter nitrogen-powered arm (fifth arm, center of image). (From Parekattil SJ, Gudeloglu A, Brahmabhatt J, et al. Robotic assisted versus pure microsurgical vasectomy reversal: technique and prospective database control trial. *J Reconstr Microsurg.* 2012;28:435–444.)

potential for an unparalleled visual acuity for complex microsurgical procedures.

Other microsurgery-specific robotic instrumentation, of potential interest to reconstructive microsurgeons, include the flexible drop-in Doppler (Vascular Technology Inc., Nashua, NH) designed specifically for use with the robotic platform. It is easily manipulated by the robotic forceps, and allows the surgeon to perform real-time Doppler monitoring of the surrounding vasculature and tissue. Also, a robotically controlled ultrasound transducer (Aloka Inc., Wallingford, CT) has recently been developed and allows surgeons to obtain full ultrasound imaging with real-time flow mapping.⁶¹ Another potentially useful modality is hydro-jet dissection, utilizing a thin, high-pressure stream of water for fine tissue dissection while preserving vascular integrity; this technology can be applied robotically with a pressure-adjustable device such as the ERBEJET2 hydrodissector (ERBE Inc., Tübingen, Germany).^{62,63} Finally, CO₂ laser dissection, which is currently growing in popularity as it can provide effective ligation and coagulation with less collateral thermal damage,⁶⁴ has been integrated into a flexible fiber-optic delivery system manipulated with a robotic handpiece attached to a robotic arm (FlexGuide ULTRA and BeamPath Robotic Fiber, OmniGuide, Cambridge, MA). The fiber-optic CO₂ laser might even substitute monopolar or bipolar cautery for microsurgical dissection, where maintaining the integrity of the surrounding

structures is crucial. As the use of robotic microsurgery expands, so will the refinement and development of new and adapted instrumentation.

Conclusion

Minimally invasive techniques have long been known to reduce postoperative pain, hospitalization duration, patient recovery time, infection risks, and overall cost, increasing the quality of care.⁶⁵ Robotic technology is the next step in the evolution of minimally invasive techniques, adding enhanced precision and visualization that can augment the capabilities of plastic surgeons and aid them in achieving safer and more precise interventions. Additionally, these technologies can enable surgeons to perform approaches never before possible, such as the robotic LD harvest. Robotic instrumentation is also expected to continue to improve and expand the range of applications in various areas within plastic surgery, especially microsurgery, leading potentially to the refinement of procedures and wider adoption. The future of robotics in plastic surgery is promising. With improved technology platforms, improved training pathways and the inevitable decreases in cost which accompany the democratization of all technology revolutions, robotic plastic surgery will likely grow and flourish.

Telemedicine and simulation in plastic surgery

Joseph M. Rosen and M. Lucy Sudekum

SYNOPSIS

- This chapter describes the latest innovations in simulation and telemedicine and their integration into plastic surgery practice.
- Simulation will have its greatest impact on the teaching and performance of plastic surgery. Simulation is used to train plastic surgery students, residents and fellows in all procedures, and to train senior surgeons on new procedures. Simulation provides an increase in safety and reduction in medical errors, since trainees will effectively “make mistakes” on a simulator, rather than on live patients.
- Telemedicine will have its greatest impact on plastic surgery delivery. Telemedicine can make use of simulation and new technology to deliver medical care to a distant population, whether during everyday life, in wartime, or following a disaster.
- This chapter will provide plastic surgeons with a basic understanding of how to apply current technologies to enhance their armamentarium with solutions to clinical and surgical problems.

Introduction

Medical technology can help doctors to diagnose, heal, and transcend traditional limitations of the human body, via tools like pacemakers, ventilators, artificial hips, three-dimensional (3D) body imaging, and even robotic arms. Plastic surgery, a specialty that prides itself on approaching complex problems with innovative solutions, has an opportunity to lead the medical community in the responsible and creative use of new technology.

Surgeons can enhance their practice with biological technologies, such as transplantation and tissue engineering, covered in Chapters 12, 16, 30, 32, 33, or with nonbiological technologies. This chapter discusses the latest innovations in nonbiological technologies – simulation and telemedicine – and their widespread integration into plastic surgery practice. Simulation is used to train plastic surgery residents in common procedures, and to train senior surgeons on new procedures. Simulation promotes safety, as trainees will make initial errors on a simulator before operating on live patients. Finally, access

to mobile sophisticated technology via smartphones has placed telemedicine in the hands of a larger population than has been previously imagined.¹ This aspect of telemedicine delivers medical care to a distant population, whether during everyday life, in wartime, or following a disaster.

This chapter will provide plastic surgeons with a basic understanding of how to apply current technologies to enhance their armamentarium with solutions to clinical and surgical problems. Technological tools can resolve needs that are not met with current standards of care (for example, a potentially concussed football player can consult with a neurologist via telemedicine without leaving the playing field).² However, it is critical that both outcomes and costs be considered whenever we evaluate new technology; the outcomes should be demonstrable, and the cost-benefit ratio considerable.

Simulation

Access the Historical Perspective section and Fig. 35.1 online at

<http://www.expertconsult.com>

Introduction and definition of simulation

Simulation is increasingly utilized in surgery as the field reacts to continued pressure to standardize training. The main push for standardization comes from the desire to improve patient safety. Simulation can be defined as “the imitative representation of the functioning of one system or process by means of the functioning of another.”⁹ This includes the use of a model, whether physical or logical, over time, to gain insight into the way the system or process operates in order to evaluate and analyze it.⁷ This chapter’s focus is on computer-based simulators that engage the learner and test cognitive knowledge. Animation is a new feature that accompanies some computer-based simulators. Trainees first watch animated computer films, to view the specific procedure and

Historical perspective

Simulation has been used for centuries in various arenas. One early example includes military simulation in the sixth century in the form of the chess game.³ Widespread use of simulation across the aviation field draws the highest correlation with the field of medicine. Link created the first flight simulator in 1929 with the goal to develop a safer, less expensive, easier method to learn to fly.⁴ The US military served as the early investor of Link trainers in World War II, and later spurred the propagation of more complex simulators for flight training upon the advent of computer imaging.⁴ Later the National Aeronautics and Space Administration (NASA) invented modern virtual reality. These tools became ingrained in training regimens for both pilots and other members of the flight crew, and also

served as a method for personnel evaluation. Contemporarily, flight simulators have proven to be not merely safe, but cost-effective, with cost ratio estimates of 1:40 for training with a simulator versus training in an aircraft.⁵

The earliest record of surgical simulators from 600 BC in India includes clay and leaf models for forehead-flap nasal reconstructions (Fig. 35.1).⁶ Other early examples of simulation in plastic surgery include Le Fort's use of cadavers to study facial fractures, and Rad Tanzer's use of plaster ears prior to completing reconstructive surgery on patients.⁷ Today medical device companies and technology are merging to create new horizons for simulating surgery and its modeling – for example, plastic surgeons can 3D-print patient models for precise surgical planning.⁸

Fig. 35.1 Early surgical planning using modeling clay for nose flap. (Courtesy of Joseph Rosen, MD.)

become familiar with the relevant anatomy, before they practice the procedure on the computer-based simulator. This is analogous to the “see one, do one” approach for traditional surgical training.

Simulation can be implemented in three phases, based on the American College of Surgeons (ACS) plan for general surgery trainees: (1) it can be used to learn skills; (2) to practice and understand procedures; and (3) to practice team training in the operating room.⁷ Simulators, physical devices which manifest simulation in the medical area, can take various forms, including bench models, animal models, cadavers, mannequins and computer and online simulators.⁷ Specialized surgical skill workshops have reduced the rate of complications in endoscopic carpal tunnel procedures.¹⁰ Thus, when applied to medical procedures, ethically and practically, simulation provides an effective tool for both education and planning in a variety of surgical specialties. In plastic surgery, simulation has applications in residency training, maintenance of certification, and patient-specific planning of procedures. Simulation provides a safe and consistent way for plastic surgeons to improve and verify technical skills, cognitive knowledge, and teamwork.

Rationale for using simulation for plastic surgery and evidence of its utility in surgical training paradigms

Both the Accreditation Council for Graduate Medical Education and American Board of Medical Specialties sanction the common six core competencies for all surgeons: (1) medical knowledge; (2) patient care; (3) interpersonal and communication skills; (4) professionalism; (5) practice-based learning and improvement; and (6) systems-based practice.¹¹ Despite these aims, the Institute of Medicine reported that roughly 210 000–400 000 deaths in the US occur each year as a result of medical errors – significant enough to deem it a public health risk.¹² These staggering statistics have prompted greater concern for patient safety across the field. Furthermore, the rising cost of healthcare has put pressure on medical centers to alleviate costs. While operating room time has real costs up to thousands of dollars per hour,¹³ simulation provides a safe way for surgeons to practice procedures at a significantly reduced cost.⁷

Using virtual reality and simulation, residents and attending surgeons can practice skills and procedures without risk to the patient; it is a supplement to the “see one, do one, teach one” paradigm. If a trainee can practice certain skills and procedures on a simulator, operating room times can be reduced, and potentially fewer mistakes made by trainees, thereby increasing patient safety.

The role of simulation in plastic surgery

Training simulators

Simulation for training is growing in pervasiveness in plastic surgery, with early use in residency programs. While the ACS has pioneered the foundational structure for using simulators for training through its Accredited Educational Institutes (AEIs) consortium, the plastic surgery community has primarily focused on developing procedural simulators specific to the field. Technical skills are usually taught in general

Fig. 35.2 The Mimic dV-Trainer simulator for robotic surgery is designed to train surgeons in how to use the da Vinci surgical system and to teach system awareness, instrument manipulation, and basic skills such as needle handling and energy management. **(A)** The Ring Walk exercise assists in refining dexterity, moving an object with a linear constraint, using the camera to navigate around the surgical field, and learning how to use the clutch with the instruments. **(B)** The Energy Dissection exercise instructs the user in applying the use of cautery and coagulation as part of dissection, as well as controlling blood loss. (Courtesy of Jeff Berkley, PhD, and Gordon Nealey; copyright 2012 Mimic Technologies, Inc.)

surgery training; the AEIs aid this process with skills simulators such as box trainers for suturing.¹⁴

As minimally invasive robotic surgery gains traction, simulators are likewise utilized to train on specific operating tools, such as the da Vinci system. The Mimic Technologies dV-Trainer, a simulator for the da Vinci system, is a tabletop virtual environment with a two-handed haptic device with force feedback and tracking (Fig. 35.2). A study by Kenney *et al.* revealed that the dV-Trainer had content, construct, and face validity, which is a positive assessment of the simulator’s realism by the novice user.¹⁵ Intuitive Surgical also offers the da Vinci Skills Simulator, introduced in 2011. Designed to offer an immersive virtual experience via the surgeon console, the da Vinci simulator enables users to measure and track skills assessment without the need for additional system components, instruments, or skills models. The use of

simulators for robotic surgery training is explained in more detail in Chapter 34.

The American Council of Academic Plastic Surgeons (ACAPS) *Ad Hoc* Committee on Virtual Reality and Simulation for Plastic Surgery Education is committed to helping develop and distribute simulators to educate residents on plastic surgery procedures. The Committee is divided into groups of experts in four plastic surgery subspecialties: (1) craniofacial; (2) cosmetic; (3) reconstructive; and (4) hand procedures. A survey completed by 85 ACAPS members in February 2009 indicated that 93% were interested in using a 3D surgical simulator system for training residents in plastic surgery. Today this is a reality.

The Committee's goals are to adapt this advanced virtual surgery simulation technology for standardized teaching, and for procedures in the four aforementioned areas of expertise. Using a process called cognitive task analysis, procedures such as open carpal tunnel release and reduction mammoplasty are broken into steps, which are weighted according to their relevance to the outcome of the procedure. For instance, in the latissimus dorsi procedure, flap positioning and chest closure are weighted at 20%, while dressing is 5%. In this way, key teaching points are emphasized in the developed simulator.

BioDigital Inc. and the NYU Institute of Reconstructive Plastic Surgery have undertaken the development of animators and simulators to educate residents in plastic surgery procedures. Using a multidisciplinary team of plastic surgeons as medical experts, artists to provide realism, and computer scientists for technical development, the team has created a library of training programs to teach craniofacial and breast procedures. Table 35.1 summarizes the procedures for which animations have already been completed.

The SmileTrain and BioDigital cleft lip and palate simulator, developed under the leadership of Dr. Roberto Flores, MD, is an online platform allowing the user to explore the procedures in depth online (Fig. 35.3). Its CT-based patient model enables the trainee to practice, record, and review surgery in real time; to explore the anatomy at every tissue layer; and to cut surfaces, create flaps, and transpose tissue.^{16,17} Simulators in the *Interactive Craniofacial Surgical Atlas*, created under the direction of Joseph McCarthy, MD, include the frontal orbital advancement simulator, the Monoblock advancement/distraction simulator, and the Le Fort III

Table 35.1 Completed surgical animations for various surgical procedures

Problem	Animated procedure
Bilateral cleft lip	Cutting bilateral procedure
Secondary cleft lip nose	Dibbell procedure
Unilateral cleft lip	Mohler procedure
Cleft palate	Furlow (primary palate)
Genioplasty	Sliding genioplasty Jumping genioplasty
Prognathia	Bilateral sagittal split osteotomy Vertical ramus osteotomy
Temporomandibular joint ankylosis	Transport distraction
Maxillary hypoplasia	Le Fort I
Midface deformities	Le Fort III classic and distraction
Upper two-thirds hypoplasia	Monobloc distraction Monobloc classic
Craniosynostosis	Fronto-orbital advancement
Breast reconstruction	Pedicle TRAM reconstruction DIEP flap reconstruction Latissimus dorsi flap reconstruction Free TRAM reconstruction Tissue expander
DIEP, deep inferior epigastric perforator; TRAM, transverse rectus abdominis myocutaneous.	

advancement/distraction simulator. These new simulators include features such as videos of live surgeries, to help illustrate the procedure being simulated; audio voiceover, to facilitate learning as the trainee practices; and 3D visualization (Fig. 35.4). Simulators for other specialized procedures include a simulator for latissimus dorsi myocutaneous flap with tissue expander for breast reconstruction following mastectomy (Fig. 35.5).

For example, the University of Wisconsin has developed an Endoscopic Carpal Tunnel Release (ECTR) simulator that is being used by resident subjects (Fig. 35.6). The subjects are asked to take a pre-preparation test followed by randomization into simulation and non-simulation groups for

Fig. 35.3 BioDigital Inc./SmileTrain cleft lip and palate simulator showing a simulated patient's appearance (A) before and (B) during surgery. (Courtesy of SmileTrain and BioDigital Inc. Available online at: <https://smiletrain.biodigital.com/#/>.)

Fig. 35.4 MyFace craniofacial virtual surgery simulator (A) bilateral sagittal split osteotomy procedure and (B) LeFort I procedure. (Courtesy of MyFace, Joseph G. McCarthy, MD, and BioDigital Inc. Available online at: <https://civapro.biodigital.com/#/>.)

comparison. The simulation group uses the simulator, which focuses on surgical indications, relevant anatomy, and procedural steps, followed by a physical model simulation and a post-preparation test. The non-simulation group prepares for the case as they would for any other surgical operation. All subjects undergo a real-time ECTR case with the senior author and are assessed on a 20-point objective scoring measure: operating set-up, anesthesia, tourniquet, procedure steps, dressing application, etc. The subjects had different surgical backgrounds but overall it was found that the simulator group outperformed the non-simulation group on post-preparation test scores (89% vs 74%; $p < 0.001$) and operative scores (96% vs 79%; $p = 0.002$). The subjects showed significant improvement in all steps of the operation except for dressing application. This study and those like it show the promise and future of surgical training and its benefits (B. Mandel, personal communication).

Arguably the most advanced simulation system available to surgical trainees is the Wide Area Virtual Environment (WAVE) that was developed by Alan Liu at the Val G. Hemming Medical Simulation Center of the Uniformed Services University of the Health Sciences (A. Liu, personal communication). The WAVE is a 1000 sq ft immersive virtual-reality training environment that combines 3D virtual environments with patient actors, human patient simulators, and the theatrical effects to provide comprehensive and unprecedented levels of realism (Fig. 35.7). As seen in Fig. 35.7A, projectors are placed around the training operating theater and triage area allowing for constantly changing scenarios.

Fig. 35.5 BioDigital Inc. latissimus dorsi simulator. (Courtesy of BioDigital Inc.)

The WAVE is designed to support training scenarios of up to 96 hours in duration.¹⁸

Investigators at Dartmouth's Thayer School of Engineering have conducted team-training research to enhance communication and ensure safe patient handoffs between operating room personnel and hospital staff. The envisioned system – a computational team-training simulation – will seamlessly monitor medical operations to reduce or prevent catastrophic medical errors and to improve patient safety (E. Santos, personal communication). The Santos team models reasoning among doctors, nurses, and patients,¹⁹ and simulates the team's clinical decision-making and reasoning prior to, during, and after surgical procedures, to analyze inconsistencies or gaps in the procedure – a key indicator of medical errors – with the goal of alerting the team when any discrepancy occurs.

Surgical planning simulators

Plastic surgeons can use simulation not only to practice new procedures on a virtual patient, but also for patient-specific surgical planning. Prior to the first US near-total face transplant procedure, performed by a surgical team led by Dr. Maria Siemionow at Cleveland Clinic in 2008, the surgeons used anatomical models made from the patient's CT scans,

Fig. 35.6 Endoscopic Carpal Tunnel Release (ECTR) simulator. (A) Simulator set-up. (B) Detailed simulator set-up. (C) Simulator in use. (D) Comparative OR set-up. (E) Simulator in use with simulator screen and OR comparison. (Courtesy of Benjamin Mandel, MD; Steve Kempton, MD; Jacqueline Israel, MD; A. Neil Salyapongse, MD.)

Hemming Simulation Center, USUHS.)

Fig. 35.8 The stereolithographic anatomical model based on the computed tomographic scan of the patient who had the first US facial transplant, performed by a team of surgeons led by Dr. Maria Siemionow at the Cleveland Clinic in 2008. **(A)** Frontal view of the craniofacial defect after gunshot injury to the patient's face, indicating damage of the frontal and midface skeleton including the infraorbital floor and the nasal, zygomatic, and maxillary bones mixed with the metal pieces. **(B)** The left side of the defect, with a significant tridimensional defect showing missing nose and nasal bones and upper jaw bony support. **(C)** Frontal view at 6 months after transplantation, demonstrating complete restoration of the craniofacial defect by replacement of all missing bony components of the facial skeleton and soft tissues of the patient with the composite facial allograft from the donor. **(D)** Left-side view after transplantation confirming restoration of the tridimensional defect of the craniofacial skeleton, including nose and bony structures supporting the upper and midface skeleton. (Reproduced with permission from Siemionow MZ, Papay F, Djohan R, et al. *First U.S. near-total human face transplantation: a paradigm shift for massive complex injuries*. *Plast Reconstr Surg*. 2010;125:111–122.)

showing the facial defect, as part of their surgical planning (Fig. 35.8)²⁰ (M. Siemionow, personal communication).

Prior to the second US facial transplant, performed by microsurgeons at Brigham and Women's Hospital in 2009 under the leadership of Dr. Bohdan Pomahac, the team also used CT scans of the recipient's head and facial defect to generate a life-sized 3D model of the cranium, built in acrylic. The team then generated a second 3D facial model, based on a CT scan of normal facial anatomy, from which parts were removed and transferred to the recipient's model. This allowed the surgeons to plan how much bone was needed from the donor, as well as to anticipate the anatomical logistics of the donor recovery procedure (B. Pomahac, personal communication).

Future applications of simulation

A future vision must include simulation trainers in plastic surgery plans universally, and also provide training for new procedures as part of continuing education, in a safe, efficient, and effective manner. As simulation centers are developed in increasing numbers, and medical center and surgery curricula continue to incorporate simulation as a beneficial tool for training, simulation will become more ingrained in the field of plastic surgery for resident training, maintenance of certification, and patient-specific practice. As simulators become more advanced, they will be used at various levels in practice, and may even incorporate a physical-behavioral-genomics model of a human being, one that combines information about a person's cells, tissues, organs, vital signs, biomechanics, physiology, behavior and genetic traits, combined with the epidemiology of a larger population. Such a comprehensive model might simulate and predict the individual's behavior and health (Fig. 35.9).

Telemedicine

Access the Historical Perspective section online at

<http://www.expertconsult.com>

Introduction

In the future, telemedicine will extend robotics and simulation to make plastic surgery safer, simpler, more successful, and more accessible. The patient-provider relationship and delivery of care will be transformed by telemedicine, as doctors will not need to be physically present in order to care for their patients. This section of the chapter defines telemedicine as a clinical tool, explains the role of social networks in telemedicine, presents potential challenges in its utilization for plastic surgery, and explains current and future applications in plastic surgery.

Definition and methods

Telemedicine refers to the application of telecommunications technologies to a medical context. Telemedicine may be defined as "a branch of e-health that uses communication networks for delivery of healthcare services and medical education from one geographical location to another".³¹ Telemedicine may be as simple as faxing a copy of an X-ray, or as complicated as multipoint video conferencing across several continents with high-resolution image transfer. A resident can ask an attending physician for advice; one physician can ask another physician for advice; or a patient can ask advice of a doctor. Many components of current plastic surgery consultation can be converted to a digital format, including long-distance triage, remote consultation, telesurgery,^{32,33} postoperative assessments, patient education, continuing medical education for providers, and public health education.

Worldwide, the need for telemedicine has only increased as the gap in access to technology broadens between those living in rural and urban areas. People living in rural areas have less access to medical care generally, and in many cases, to specialty care, with the exception of medical volunteerism groups such as ReSurge International (formerly Interplast).³⁴ ReSurge International is one of a number of groups that provide temporary specialty care to remote areas on international surgical humanitarian trips, and supplement this with visiting educators who provide direct, hands-on training for local medical personnel. The interaction with local

Historical perspective

NASA helped pioneer telemedicine in the 1960s: when humans began flying in space, physiologic parameters were communicated between both the spacecraft and the space suits during missions.²¹ Fifteen telemedicine projects were active by 1975, with pioneering efforts in the US and worldwide. The earliest-reported nongovernment applications of telemedicine included a teleradiology effort at the Montreal Neurological Institute and a telepsychiatry network at the Nebraska Psychiatric Institute.²¹ Early projects using telemedicine in rural healthcare proved to have great beneficial effects on survival and recovery of patients; as the cost and size of the equipment came down and the technical quality went up, telemedicine became feasible to use in different applications, including maritime medicine and care in remote locations, including Antarctica.^{22–26}

Telemedicine has followed the enormous growth of computing and the internet from 1980 to the present day. Whereas

in 1980 almost no one had a home computer or cell phone, and the internet was in its infancy, now most people in developed countries have home computers, internet access, and mobile phones, making it possible for people to work remotely and telecommute; do online banking, travel reservations, and web shopping; and use email and social networks. A similar transformation occurred in medicine: it is now possible to link from home or a small clinic or medical center using video conferencing and other telemedicine technologies to access specialists worldwide for consultation and even surgery.^{27–29} Telemedicine is increasingly benefiting from the technology that allows us to collect and transmit medical information using portable devices such as ultrasound monitors and cell phones. For example, Remote Interaction, Consultation, and Epidemiology (R.I.C.E.) uses SMS technology to track influenza and diarrheal diseases in rural Vietnam.³⁰ Networked medical care has a great potential to improve both daily patient care and also to allow clinicians to respond to various medical disasters anywhere in the world at any time.

Fig. 35.9 Physical-behavioral-genomics model. No model yet exists that encompasses the physical body, behavior, and biomarkers of an individual, but Dr. Joseph Rosen and colleagues are developing such a model. A full human model could include a person's cells, tissues, organs, vital signs, biomechanics, physiology, behavior and genetic traits, combined with the epidemiology of a larger population. Such a comprehensive model might simulate and predict the individual's behavior and health. (Courtesy of Joseph Rosen, MD.)

providers is such that surgeons in host countries can post cases on a secure website to receive advice when ReSurge International teams are not in-country. Specialist physicians, such as plastic surgeons, are often a small percentage of the overall physician workforce and tend to be concentrated in urban centers. Through this networked-care mechanism, we are moving toward more efficient use of specialists as their time and expertise are available anywhere, anytime.³⁴

Several technologies are commonly used in telemedicine applications. The first, called store-and-forward, is used to transfer digital images from one location to another. An image is taken with a digital camera (store) and then sent (forward) to another location for interpretation and analysis (Fig. 35.10). This method is used for nonemergent situations, when a consultation can be provided in the next day or few days, and a patient's wellbeing is not dependent on an immediate response from a physician.

Another technology often used in telemedicine applications is called the synchronous model. This technology is used when a face-to-face interaction is desired, and is used between a patient/provider in one location and a specialist in another location. It provides real-time relay of information and can allow for review of information by on- and off-site personnel (Fig. 35.11).³⁵ In most cases, the patient/provider pair is located in a rural environment and the specialist is located in an urban center. These types of patient consults are becoming commonplace in medical practice. Dartmouth-Hitchcock Medical Center's Division of Plastic Surgery is developing a follow-up telemedicine program. Programs like this one are only being used when a physician-patient relationship has already been established. (See below for telemedicine regulations and legal constraints.) Once the relationship has been established, the patient can be screened and enrolled in these programs to avoid follow-up appointments at the hospital. These telemedicine visits can take the place of face-to-face clinical visits. This is both cost- and time-efficient for the patients (Figs. 35.12 & 35.13). Video conferencing equipment at both locations enables a live, real-time consultation for the patient without having to travel (Table 35.2).

Social networking

The future delivery of healthcare will not be limited to face-to-face interactions. Online social networks, such as [Patients-LikeMe.com](#) and [CarePlace.com](#), already link patients with similar conditions. Clayton Christensen, in *The Innovator's Prescription*, discusses facilitated networks as an important part of a future healthcare system.³⁶ The websites previously mentioned already exist for patients as facilitated networks. In the plastic surgery realm, [www.obesityhelp.com](#) is a website where patients can find resources on weight loss surgery, including a body mass index calculator, research, forums, insurance assistance, pictures, providers, and stories.³⁷ Facilitated networks can exist specifically for plastic surgeons, creating a space where they share best practices and support specific lines of work.

Table 35.2 Two telemedicine technologies and comparison

Type	Store-and-forward	Two-way interactive
Situations used	Nonemergent	Synchronous, often urgent or in postoperative follow-up
Present uses	Teleradiology, ultrasonography, telepathology, teleanesthesia, teledermatology	Real-time videoconferencing for patient consultations using otoscopes, stethoscopes, or presence of visiting nurses
Advantages	Requires less bandwidth	Real-time
Disadvantages	Takes longer	More expensive, requires more bandwidth

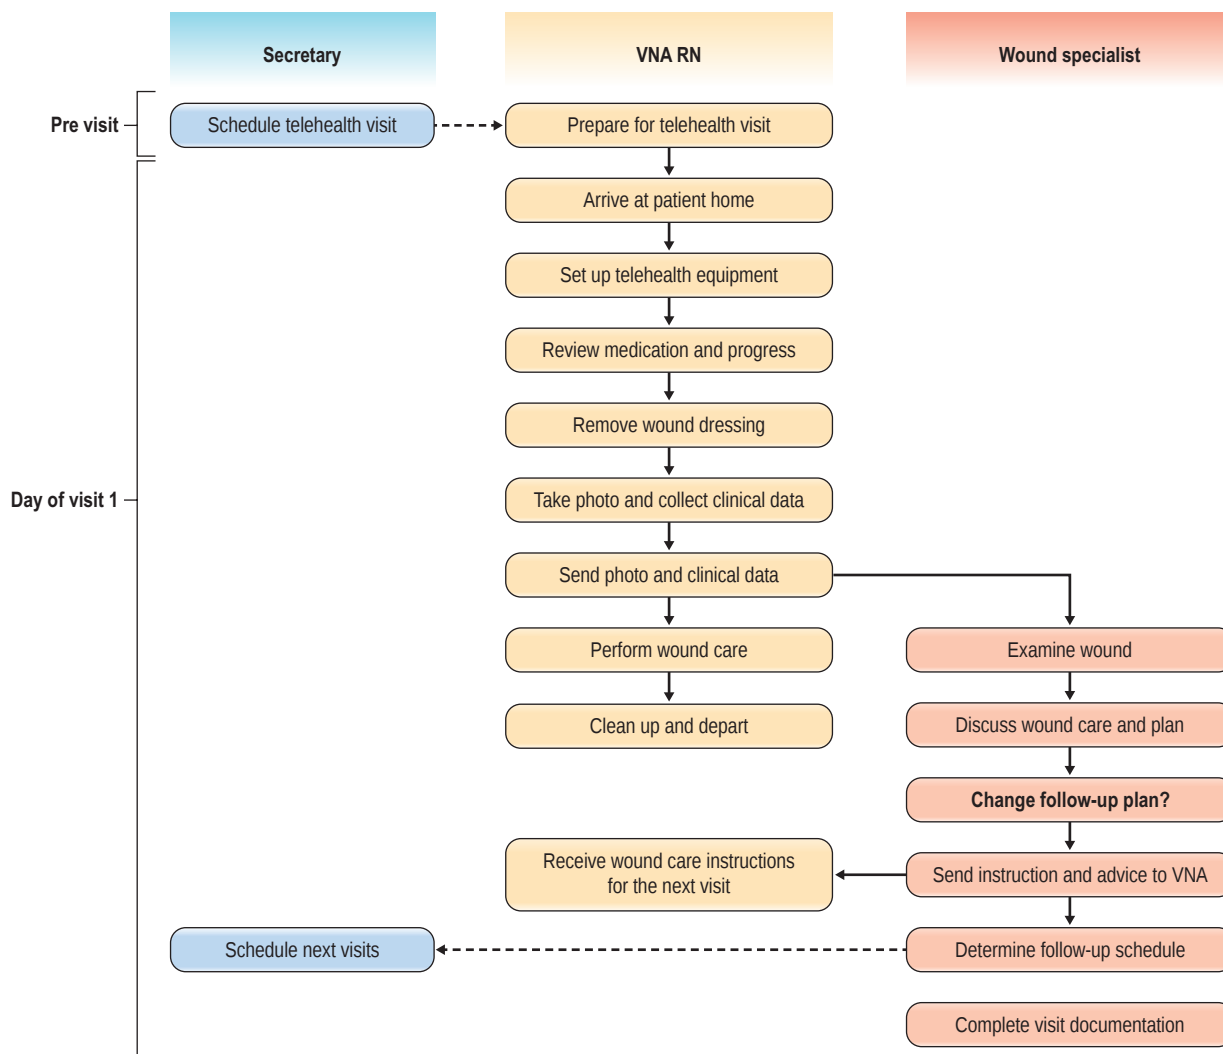

Fig. 35.10 Wound clinic telehealth “store-and-forward model” timeline. The secretary who schedules the visit communicates with a registered nurse (RN) from the visiting nurse association (VNA) to help plan and conduct the visit. The nurse then confers with a wound specialist to examine and treat the wound, and communicates back to the secretary to close the loop.

Plastic surgery and telemedicine

Plastic surgeons have used telemedicine predominantly in communicating about individual cases in the international medical arena. Telemedicine can be used in the preoperative, operative, and postoperative phases of a plastic surgical operation. Through organizations such as ReSurge International, plastic surgeons anywhere in the world receive daily updates about cases in developing nations where consultations are requested.³⁴ These surgeons can choose to log on to the online system to provide their expertise on the case. They can view patient diagnostics and past medical history, and write a case report. This is a prime example of medical care at a distance.

The other major area in which telemedicine impacts plastic surgery is in telesurgery. Using telesurgery, surgeons can operate on patients who are geographically remote: for example, a patient who cannot physically or financially afford to travel to the doctor.³² In the future, surgeons might remotely operate on an injured soldier on a battlefield,³³ or a victim of an earthquake, hurricane, pandemic, or other disaster (Figs. 35.14 & 35.15). One major advantage of telesurgery is that patients can remain in their own environ-

ment, where they can receive care and support from community or family members.

A brief description of the specific “tele” terms relating to telesurgery may help the reader. The term teleoperation means doing work at a distance. Telesurgery refers to doing surgery across a distance. For example, a surgeon, in one location, can control a surgical robot at a remote location (known as telerobotics). Telerobotics is depicted in Fig. 35.14 with a schematically drawn robotic surgeon; though in practice, a telerobotics system might look more like the da Vinci system (Fig. 35.16), with the surgeon using a control console and viewing system at his or her site, directing the actual operating robot at a remote site, which must also have a camera to send back images to the surgeon of the robot’s-eye view. Telepresence refers to being somewhere one is not physically present: the best current example is videoconferencing, which makes one “present” via two senses: sight and sound. In the surgical example, telepresence could mean an expert surgeon projecting his or her image into a remote operating room, via two-way videoconferencing, to be a mentor assisting the other surgeons in real time. The OR surgeon(s) would see the remote mentor “appearing” on a

Fig. 35.11 Wound clinic telehealth “synchronous model with video conferencing” timeline. This scenario is similar to Fig. 35.10 where the secretary communicates with the registered nurse (RN) at the visiting nurse association (VNA), who in this case conducts a telemedicine video consultation (TVC) to communicate with the wound specialist.

monitor in the OR, and the mentor would likewise see an image of the OR and surgical field. Virtual telepresence could also be employed, in which a computer-generated surgical mentor (perhaps from an animation or a simulator) would project into the actual OR to help instruct the surgeons (see Fig. 36.14).

Telemedicine for the plastic surgeon

Each state is adopting or creating its own regulations to monitor and establish telemedicine practice. Physicians using telemedicine must be licensed in the state of their established practice and the state where the patient is located, if different.

Fig. 35.12 Telemedicine postoperative consult. (Courtesy of Dartmouth-Hitchcock/Mark Washburn.)

Fig. 35.13 Telemedicine postoperative at-home consult. (Courtesy of Dartmouth-Hitchcock/Bonnie Barber.)

Fig. 35.14 Telesurgery and telepresence are two ways in which a remote surgeon can assist in, and/or direct procedures in, an operating room (OR) anywhere else in the world. In telesurgery, the remote surgeon controls a robot that actually conducts the surgery. In telepresence, the remote surgeon serves as a mentor to instruct the surgeons in the actual OR, using two-way videoconferencing (alternately, a computer-generated, animated or simulated surgical mentor is projected into the actual OR). In both telepresence and telesurgery, the remote surgeons see a view of the actual OR with images collected by camera and transmitted in real time.

Fig. 35.15 Telesurgery via satellite using haptics and robotics. Image depicting conceptualization of how surgeons might someday conduct surgery from Earth to space. (Courtesy of Joseph Rosen, MD.)

Nationally, the American Medical Association's Code of Medical Ethics has been challenged to include telemedicine because of a key issue: does telemedicine allow for a patient-physician relationship? The current law in New Hampshire allows physicians to establish a patient-physician relationship and prescribe medications via telemedicine. Prescribing drugs without such a relationship is not allowed, except under certain conditions, including newly hospitalized patients. Most controlled substances may not be prescribed by telemedicine.³⁸

Ubiquitous mobile telemedicine

There are significant barriers to overcome before telemedicine can be incorporated ubiquitously. We must demonstrate its cost-effectiveness; resolve insurance reimbursement issues; resolve legal issues regarding licensing of physicians working across state and international lines; and provide sufficient internet connectivity and bandwidth. Telemedicine technology will be important in the ongoing healthcare debate, as it promises to provide a potentially higher quality of care at a decreased cost.

Telemedicine has the potential to transform the role of the plastic surgeon as a provider, by making access to care both cheaper and faster as part of a networked healthcare system. Providers will not have to receive teleimages over email or be physically present in a room with expensive video conference

Fig. 35.16 da Vinci Si high-definition robotic surgical system, showing two surgeon consoles, patient cart, and vision cart. (Courtesy of Intuitive Surgical and © 2012 Intuitive Surgical, Inc.)

Fig. 35.17 Smartphone medical applications. (Courtesy of Joseph Rosen, MD.)

equipment, but will be connected to a network through mobile handheld devices that allow them to acquire data and diagnostics about a case, formulate a patient plan, supervise surgery, and perform consultations in real time.

Technological convergence

The reconstructive ladder for the 21st century is one in which the plastic surgeon is able to weigh the risks and benefits associated with fixing a deformed limb or face with many choices: through reconstructive surgery, using microsurgical techniques; or through replacement using either robotic prostheses, a human tissue transplant, regenerative medicine, or tissue engineering.

Diagnostics, therapeutics, and networking are all being supported by robotics, simulation, and telemedicine. These technologies depend on information technology/information management bandwidth, speed and processor power, all of which will become better, faster, and cheaper. Given the wide use of smartphones and the abundance of medical “application” development, patients, physicians and plastic surgery trainees can explore different aspects of healthcare at their fingertips (Fig. 35.17). The website, iMedicalApps.com reviews medical “apps” and telemedicine technology that are at the forefront of innovation.^{39,40} The developers of iMedicalApps.com have since developed iPrescribeApps.com, a website that can allow physicians to prescribe an app for patient use.^{40,41} We will be able to make diagnostic decisions from smaller and smarter devices, linked to a larger network, and these devices’ capabilities will increasingly converge. It is now possible to access the *Plastic and Reconstructive Surgery Journal* from a desktop computer, laptop computer, and even an iPhone or Android device. In the future, it will be downloadable on an iPhone and viewed remotely while participating in telemedicine over the phone or another handheld device.

Fig. 35.18 Healthcare of the future as a network centering on Cybercare development. EMR, electronic medical record. (Courtesy of Joseph Rosen, MD.)

Conclusion

Over the next ten years we will see a dramatic reduction of cost in information technology and a steady increase in computational power. This will result in a significant improvement in the ease of using these technologies in our practices. Information technologies will take many forms, from the two that we have just discussed, simulation and telemedicine, to many others. We use the term “Cybercare” to encompass the many different information technologies in medicine that will impact plastic surgery (Fig. 35.18).

At present, each of our practices and institutions are incorporating electronic medical records. These initial systems have created significant barriers to our practices with respect to cost and time. In the future, these information systems will incorporate both simulators and telemedicine. They will also incorporate intelligent agents and artificial intelligence to improve our ability to do our jobs and increase our safety. Intelligent agents can be incorporated within these systems to follow a lab value and make sure that we see this result and respond to it in an appropriate manner. Artificial intelligence can aid us in making the right decision about which antibiotic to use, and make sure that we do not give the wrong

Fig. 35.19 Evolution of healthcare from hospital-centric to user/patient-centric network. (Reprinted with permission from Rosen JM, et al. *Cybercare 2.0: meeting the challenge of the global burden of disease in 2030*. Health Technol (Berl). 2016;6:36.)

Fig. 35.20 The clinic visit of the future where the patient and the physician can visualize and interpret medical records via virtual reality lenses. (Reprinted with permission from Rosen JM, et al. *Cybercare 2.0: meeting the challenge of the global burden of disease in 2030*. Health Technol (Berl). 2016;6:36.)

medication to a patient who may have an adverse reaction to that drug. For example, Watson by IBM is challenging how we diagnose and treat cancers.⁴²

Our practices will shift from the hospital to clinics to the home. Plastic surgery has been the leader in providing high-quality surgical care in an outpatient setting. This trend will continue. And instead of the patient coming to the hospital, information and decision-making will shift from the hospital to the clinic to the home (Fig. 35.19). Care will follow a network and patients will share information on social media and the internet. This should result in improved care at a decreased cost. A physician can provide care anywhere within

this network through telemedicine, by phone, by teleconference, by wearing a virtual reality interface, or by being within a virtual reality WAVE (see Fig. 35.7).

The physician of the future may see a patient using a virtual reality interface, like Google Glass. When additional information is provided through this interface, we call it augmented reality (Fig. 35.20). This will provide additional information about the patient from the electronic medical record, outside records and up-to-date literature. And at the same time the patient can wear an interface to help them to better understand the planned procedure. The patient interface could have a simulation of the procedure that explains the procedure to the patient step-by-step.

Over the next ten years, the delivery of healthcare and plastic surgery will be transformed by information technology. It will take many forms, and it will have a learning curve that each provider will face, but eventually there will be an improved system that provides better outcomes for the patient with increased safety.

Acknowledgments

We also wish to extend thanks to the various doctors and product developers who helped review the chapter and provided comments, content, and images.

Digital technology in plastic surgery

Lynn Jeffers, Hatem Abou-Sayed, and Brian Jeffers

Introduction

Advances in digital technology have impacted and will continue to impact plastic surgery. This chapter will explore the effects of current and future technology on the patients' and doctors' experiences: (1) prior to the plastic surgery consultation, (2) during the patient encounter(s), (3) in the operating room and during the perioperative period, and (4) during long-term follow-up. The chapter will also discuss the impact of digital advances on education, research, medical devices, patient monitoring, "Big Data" analytics, and registries.

Digital technology before the first consultation

Introduction

Digital advances have expanded the base of knowledge available to patients such that even before consulting with a doctor, patients can become well informed about procedures, the selection of available surgeons, and the methods used to make an appointment. A plethora of informational websites are available to educate patients on procedures, postoperative recovery, surgical limitations, and other information needed to ensure the patient arrives at the consultation prepared and knowledgeable.

Information on procedures

Using online databases and websites, patients can learn more about the procedures they might undergo before speaking with a physician. Informational websites and applications can allow patients to compare and differentiate between various procedures. By examining the descriptions and exact procedures of different operations, patients can analyze the inherent risks and dangers. Websites such as www.smartbeautyguide.com can aid patients in choosing a procedure, understanding

potential complications, and even finding a surgeon whose office is geographically convenient to the patient. The availability of this information can produce a more informed patient and a more efficient and effective consultation with the plastic surgeon. Some applications allow the patient to visualize simulated results through 3D animation and may produce full 3D models through the interpolation of several 2D pictures, which can be uploaded by the patient to the website before seeing the plastic surgeon. The patient must visit the physician to see the 3D images. Online content on plastic surgery websites often includes animations designed to educate patients on the conduct of surgical procedures in an abstract manner for those who may not be able to tolerate video content documenting real surgery.^{1,2} For patients seeking more detailed video content on planned procedures, many surgeons create custom video content and post it to YouTube.com or other sites, along with links from the surgeon's website to the videos.

Plastic surgeons can also permit prospective patients to access certain office documentation to save time in the office for both patients and the surgeon's staff. These documents may include office policies and procedures, general consents to treatment, HIPAA privacy notifications, Patient Bill of Rights documents, intake questionnaires, menus of services, pricing lists, surgeon biographies, procedural brochures, financial policy disclosures, and others. By having prospective patients fill out these forms online or print them out and bring to the visit, the intake process at the initial consultation becomes more streamlined and more efficient for all involved. Consequently, the patient may arrive for a consultation having extensively researched the plastic surgeon's practice and the local marketplace dynamics, prepared with preliminary forms and materials, and armed with numerous questions and an idea of what he or she desires.

Choosing a surgeon

Patients considering plastic surgery can search the internet for detailed information on surgeons and their practices, their

credentials, price estimates for procedures, patient satisfaction testimonials and outcomes culled from review sites, and galleries of preoperative and postoperative photos.

Patients often research a plastic surgeon's credentials and reputation before choosing a surgeon by reviewing the practice's website as well as a number of review sites.³⁻⁷

These sites not only provide patients with a forum to share their perceptions of the quality of the surgical outcome, but also the quality of customer service, the appearance of the office, and the friendliness of the staff, etc. These sites can give patients significant influence on the reputation of the doctor or practice, which can be detrimental or advantageous. However, the entirety of the surgeon's online presence including videos, media appearances, blogs, Facebook, etc. help to shape the surgeon's and practice's brand⁸ and, thus, it is important that the surgeon continually monitor his or her presence on the web either with a third-party service or by setting targeted Google alerts.

Patients may seek procedure pricing information to comparison shop among practices by soliciting online fee schedules and can compare menus of services where available. This information is occasionally available directly on a practice's website or can be explored on specific apps and portals.⁹ One study demonstrated that patients were more likely to book surgery at the time of the initial office visit if they knew the price of the procedure before arriving for the consultation.¹⁰

Patients can also evaluate a surgeon's results by evaluating before-and-after photos that the surgeon displays online. These galleries of before-and-after photos provide real examples of the surgeon's work and are often categorized by body location and procedure. Some programs¹¹ allow galleries to be accessed only via a password-protected patient portal that requires prospective patients to register before being

granted access (Fig. 36.1). Photo galleries can represent a meaningful component of plastic surgery marketing while also serving an educational purpose for the public. Some plastic surgeons who do not favor placing patient photos online nonetheless may provide guidance to prospective patients to contact the office for an in-person consultation, where these photos, deployed either in bound albums or using digital tools (tablets, large screens in viewing rooms, waiting-room results reels in PowerPoint presentations), are available for viewing in a controlled environment.

After selection

Once a patient has selected a plastic surgeon's office for a possible consultation, the online experience can be augmented with real-time chat tools on the surgeon's website and calendar integration via sites that permit the patient to find open appointment timeslots in the surgeon's office schedule and book visits online, with the appointments automatically populating the office practice management software system¹² or via the patient portal of some electronic health records (EHRs) with this capability.¹³ Voice-over-Internet-Protocol (VoIP) systems allow offices to communicate with patients even asynchronously to open office hours, from most mobile devices and from most locations, obviating the need for fixed landline telephone systems. Online maps with directions shareable to mobile devices or in-dash navigation systems in automobiles streamline the process of finding the doctor's office, with dynamic updates on traffic patterns available in apps like Waze (now a part of the Google Maps toolkit).

Patients wishing to travel for surgery and those who have limitations on the ability to see a physician in the office during convenient office hours may benefit from applications

that facilitate virtual consultation.¹⁴⁻²¹ One Harris poll commissioned by a prominent telemedicine vendor in 2014 indicates that 64% of consumers are willing to see physicians via video consultation.^{22,23} The Federation of State Medical Boards has issued model legislation aimed at encouraging standards in the credentialing and licensure oversight for providers of telemedicine services in participating states.²⁴ Some states do not permit telemedicine consultations, and insurance reimbursement models and legal considerations are undergoing significant debate. Nonetheless, the promise of mobile technologies in the field of telemedicine is substantial and in 2013, three companies alone hosted 400 000 to 500 000 doctor–patient interactions.²⁵ For the plastic surgeon, there are opportunities to potentially rule out poor candidates for surgery before they incur the expense of traveling to the surgeon's office, or to permit office staff to begin the intake and preoperative workup process for remote patients, or to provide a more personal introduction as part of marketing outreach to bring in more patients.

Patients who require urgent but non-emergent care (for example, for minor burns or other minor trauma) also have tools for finding local clinical resources via applications similar to “sharing economy” tools like Uber. Some innovative apps²⁶⁻²⁸ provide logistics for connecting patients with available providers on demand, creating a digital platform to reimagine the “house call” of old, or allowing patients to bypass costly points of care like emergency rooms and arrange services in the office.²⁹

Digital technology during the office visit

During the consultation encounter, digital technology can enhance: (1) patient information gathering and archiving in the form of electronic medical records including patient data, medical information, photographs, and documents; (2) patient education via digital materials; and (3) clinical information and decision-making.

Medical records

Choosing an electronic health record (EHR)

The Health Information Technology for Economic and Clinical Health (HITECH) Act, enacted as part of the American Recovery and Reinvestment Act of 2009, was signed into law on February 17, 2009. Starting in 2011, eligible professionals could receive incentive payments up to a total of 5 years if they could demonstrate “meaningful use” of certified electronic health records (EHRs). Providers faced up to 5% penalties if they did not demonstrate meaningful use beginning in 2015. As a result, adoption of electronic health records increased during this time.³⁰⁻³⁴ Even plastic surgeons who do not treat many Medicare patients have increasingly adopted electronic health records and practice management software. The EHR market continues to evolve. The market is anticipated to consolidate, as rules, regulations and functionality demands increase in this space. However, many EHRs were designed with the primary care physician in mind and thus can be lacking in key features desired or required by the average plastic surgeon. In addition, many programs require a significant upfront investment of

both time and money. Physicians and office staff may experience challenges in implementation and training with new EHR systems, sometimes with a considerably steep learning curve, requiring significant allocation of staffing time before the EHR is fully operational for the office's needs. Thus, the choice of EHR can be crucial. Below are some key considerations regarding the EHR itself that should be taken into account when choosing an EHR system.

Certification

Determining whether the chosen EHR is certified by the ONC (Office of the National Coordinator of Health Information Technology) is important, especially if the plastic surgeon is planning on participating in certain government incentive programs. Certification is meant to assure that the EHR system offers the capability, functionality and security to meet the Meaningful Use (MU) criteria established by the Centers for Medicare and Medicaid Services (CMS).³⁵ The Meaningful Use program is in the third of three “stages” of implementation along an 11-year timeline (culminating in the final Medicaid incentive payments being slated for 2021), with penalties to be levied against practices which see significant Medicare or Medicaid volume and fail to demonstrate compliance with MU. Certification provides one level of reassurance that the EHR system allows entry of data necessary to achieve MU compliance and is a toolkit for submission of reports to CMS for validation and incentive processing. For plastic surgeons not interested in participating in the Meaningful Use program, certification may provide some level of assurance that the program meets certain standards of functionality, security, and interoperability, and probably is more likely to survive consolidation than other non-certified programs.

Server on site or off site or subscription model (SAAS – Software As A Service)

There are three principal models through which an EHR program can be provided to users. Some EHR vendors can be deployed all three ways. The most traditional model of software delivery houses the program and data on a server in the office owned by the physician/group. The physician has complete control of the data, but is responsible for hardware maintenance, back-ups, insurance, and security, as well as manual updating of the software. Access from a remote location or satellite offices is also maintained by the physician's practice, and may involve high-speed data access lines (T1 or fiber-optic cable, for example), virtual private networks (VPNs), and other remote logging programs. This model may require higher upfront costs for hardware infrastructure and, depending on the size of the practice, one or more IT specialists outsourced or employed in-house. Another model involves using a server that is housed off-site, maintained by a third-party vendor. The physician/group still maintains complete control of the data but leases space in a remote server. Updates frequently still require manual effort, but responsibility for servers, back-ups, and insurance is assumed by a third-party vendor.

Finally, the Software-As-A-Service (SAAS) model is a subscription service in which the program and data are maintained and updated by the EHR vendor, with the software accessed via the computers/devices in the practice – much like the way Gmail, Yahoo! Mail, Dropbox, and other online programs

work. The updates are usually real-time and performed automatically by the EHR company, often without disrupting the software's availability. The server function, back-ups, and security of the server is assumed by the EHR company. Depending on the contract, the physician/group may incur fees to have the data extracted into a usable format when changing vendors. Some contracts and user licenses permit the EHR company access to or ownership of the data. In some cases, de-identified data (records that have been stripped of identifying personal or demographic information) can be used by the vendor for purposes of research, product development, or aggregation and commercialization. This model usually boasts lower upfront costs for hardware purchase and installation, and delivery through a cloud infrastructure facilitates easier access from remote locations and satellite offices. Increasingly, both professional and consumer software is being delivered through the SAAS model, with support, training and updates bundled into the subscription costs and availability provided "anywhere, anytime and on any device".

Stability in the market

A search of the ONC-approved comprehensive EHR list as of 2015 shows 648 approved programs,³⁶ a number that is probably unsustainable. Even in 2012, 75% of users of EHR products were concentrated among the top 6 vendors serving hospitals and the top 15 serving outpatient venues.³⁷ Accordingly, an important consideration when choosing an EHR is whether the product is anticipated to survive an expected consolidation of the market among sustainable leading vendors. Such vendors often have the advantages of consistent revenue from the installed user base along with scalable physical and human resources that may allow them to fulfill further governmental or other regulations better and to make updates and improvements to their programs. On the other hand, larger EHR companies may be somewhat less responsive to suggestions by users to improve the usability or functionality of their programs or to add features that are crucial to only a small subset of their users. As plastic surgery is a relatively small specialty, this can sometimes be an issue impeding the timely selection of an EHR with essential features needed by the average plastic surgeon.

Features and functionality

Most certified EHRs can adequately accomplish the generation of a satisfactory progress note, problem list, medication list, etc. More important is the ease of use of the software. The usability of many programs is hampered by the requirement for multiple clicks, non-intuitive navigation, and a cumbersome maze of windows and menus. It is critical to request a detailed demonstration of the functioning program and to engage with current users of the system who are reference clients of the vendor. One way to accurately experience the ease (or difficulty) of use and functionality is to have the demonstration performed in a manner that follows the practice's current workflow from initial patient contact, scheduling, registration, intake, note generation, billing, reporting, follow-up, etc.

As discussed above, many EHRs in the market were not designed with plastic surgeons in mind. Practices should carefully vet those features that may not be accessed by a general provider, including cosmetic quote generation, inventory and

point of sale management of product lines, prepayment for services (e.g., deposits and prepayment for cosmetic surgery or package pricing for lasers, etc.), photo archiving with rich search and display features (see below), patient management (see section below), and others. Contracts and user agreements that are contingent on the development or enhancement of a feature or functionality should have clearly agreed-upon language in the contract with timelines and benchmarks, along with consequences for missed milestones.

Support and implementation

Implementation, training and support are critical services provided by vendors. Important considerations include the length, complexity, cost and responsibilities for the installation process as well as the amount of initial and ongoing training included and available. Guaranteed limits on outages and unavailability of the software during updates, bug fixes and other interruptions should be sought and practices should seek clear terms regarding the support resources available in such instances, especially after normal business hours. Even something as seemingly trivial as the time zone of the vendor's support headquarters may have an impact on office productivity if the practice experiences bugs, slow data processing, access problems or other issues during normal business hours in another time zone. Many vendors provide extended hours or offer "premium" support (typically at a surcharge) to cover such contingencies. Most experts recommend that a busy practice anticipate a decrease of 50% in both productivity of office staff as well as physician volume during the implementation period of the EHR (which in some cases can last months to a year or more).³⁸ One study estimated an average of 611 hours required to prepare for implementation of the EHR, and 134 hours needed by end-users (physicians, clinical and non-clinical staff, etc.) to become sufficiently familiar with the EHR system to feel comfortable using it regularly with patients.³⁹

Contracting considerations

As with most contracts, it is advisable to have an attorney familiar with such transactions review the EHR vendor's contract, including (where appropriate and provided) Master Services Agreements, Statements of Work, and User Agreements/Terms of Use. Some specialty society and state medical societies also offer resources on this topic. Some basic considerations to delineate include:

1. Who owns the data?
2. Does the contract grant the EHR company permission to access the physician's patient data and, if so, is it in a de-identified and aggregate form and is the company permitted to sell the data to other parties?
3. Is there a required duration of contract? If so, what constitutes a breach of contract to allow the physician to terminate the agreement early (e.g., excessive downtime, lack or loss of certification by ONC, failure to create agreed-upon features, etc.)
4. When the physician changes vendors, what is the process to decrypt the data and provide it into a usable format such that it can be used in another EHR? What is the cost of the data conversion and agreed-upon timeline and redress for failure to deliver the data in a timely fashion?

5. What is the process to gain support for downtime of the program? There should be a maximum percentage set for downtime and a maximum time for resolution.
6. Is there an agreement to work with other vendors to allow for interfacing or integration of different programs (e.g., photo archiving or morphing programs, patient management systems, third party billing clearinghouses, etc.)?
7. Are there additional costs to add providers, support staff or satellite offices? Some EHR programs charge per user, others per physician (or provider, including nurse practitioners and physician's assistants), still others per computer terminal workstation license.
8. Who is responsible for installing and ensuring the functionality of the EHR program?
9. What capabilities exist for interoperability of systems – i.e., does it link to laboratory vendor data, radiology systems (PACS or DICOM viewers), other EHRs, etc., and is there an implementation or maintenance cost for these services?

Using the EHR

A comprehensive primer on the use of EHRs is beyond the scope of this chapter. However, this section illustrates some suggestions to help enhance the effective use of EHRs in a plastic surgery practice.

Intake and entry of information via patient portals and on site

ONC-certified EHRs are required to furnish a patient portal that allows patients to access limited portions of their medical record and results as well as interact with the office. Patient portals which allow the patient to enter demographic and clinical information prior to the office visit can improve office efficiency by minimizing the amount of data entry at the time of the visit. Some programs allow different questionnaires and intake documents to be created which can be tailored to specific physicians' practice preferences, or keyed to the patient category (e.g., the surgeon is likely to be interested in different information when seeing a hand surgery patient vs. a facelift patient). Demographic entry by patients permits them to update contact information and privacy permissions in a more timely and well-documented manner. Alternatively, such intake forms can be completed in the office with staff members assisting the patient with the appropriate electronic forms or performing a transcribing function for patients who have difficulty working with digital devices. Bubble forms (similar to Scantron standardized test forms but printed by the practice on regular paper) can be created and used in some EHRs^{40,41} which scan the responses into digital format directly into a progress note. Advances in optical character recognition (OCR) and natural language processing (NLP) are likely to further enhance the intake of medical information into structured medical records.

Data entry at the time of the patient consultation

Copious entry of free text at the time of the patient consultation is neither feasible nor desired. Typically, EHRs make use of a library of templates created for various patient encounters, e.g., initial breast reconstruction consultation, breast

augmentation consultation, tissue expander visit, encounter for injectables, etc. Most EHRs permit the templates to include not only the current chief complaint(s) and history of present illness with associated relevant physical exam, but also the typical discussion, treatment plan options, orders, and medical coding. These work best when there are visit categories which are more frequent for the practice, and some EHRs will build these templates at the time of implementation based on the practice's current EHR documents or paper forms being used in the practice. Certain visits might best be recorded with a visual form or on anatomic images, with annotations typed or drawn as appropriate, as is commonly done when recording injection sites for botulinum toxin and filler treatments. It is important to assess whether the EHR allows the physician or other user to create custom templates to fit the practice's regular workflows or the user's personal preferences, as opposed to requiring that requested changes or templates be submitted to the EHR company. Customization can be key to effective use of an EHR system.

With less common or complicated encounters, templates may be less helpful as real-time text editing becomes necessary. Some physicians find it helpful to enter prelim summary notations to be further clarified after the patient encounter, with the note being text-edited at a later date or the provider utilizing speech-to-text transcription in a program like Dragon Medical. Some surgeons prefer to utilize medical scribes who can enter all the appropriate information at the time of the encounter, recording observations rapidly into the EHR while the physician focuses on direct patient care and face-to-face interaction. The scribes can be the physician's employees physically present in the examination room, or may be at a remote location. One vendor¹¹ offers HIPAA-compliant scribing services via Google Glass technology, allowing the scribe to see and hear the patient encounter while transcribing from a remote location. Newer EHR products are leveraging the widespread availability of mobile technologies and Wi-Fi to facilitate less disruptive ways to use an EHR in the patient encounter (Fig. 36.2).

Alerts

Many EHR products also allow custom setting of alerts to assist with clinical decision-making or with business practice.

Fig. 36.2 Modernizing Medicine EMA Plastic Surgery. (© 2015 Modernizing Medicine, Inc., used with permission. All rights reserved. Modernizing Medicine and Electronic Medical Assistant are registered trademarks of, and EMA is a trademark of Modernizing Medicine, Inc.)

For example, some systems allow the user to set an alert which pops up whenever a specific patient chart is opened to display, for example, that this patient needs to retake her photos or pay for her most recent treatment. Most EHRs also provide alerts for medication contraindications, drug–drug interactions, and/or disease process considerations when prescribing medication. Some programs may allow the user to customize action items that only display when specific criteria are met. For instance, if a female patient is older than 50 years old and has not had a mammogram in the last year, the EHR may prompt the user to consider ordering a mammogram, and may even provide computer provider order entry that generates a printable requisition or transmits the order electronically to a radiology center.

Document and forms management

Most EHRs enable the user to upload forms that are required by various vendors and facilities, such as the OR scheduling sheet at the surgeon's local hospital or the order form for a frequently prescribed product or durable medical equipment. Some EHRs will allow the user to mark directly on the image of the form and save it as a document. Others will also allow the form to be set up to capture each blank in a form as structured data (e.g., smart PDF forms) that can later be used to generate reports or used in a mail-merge document.

Integrated systems

As much as possible, arrange for integration of the various programs that will be used in the practice. Many vendors of EHR products now offer integrated software suites that include medical records, billing, practice management, laboratory and diagnostic study results, revenue cycle management, inventory, operating room compliance documents, consent forms and surgical quotes. These systems may also feature direct data integrations or single-sign-on interfaces to the products of other vendors. For instance, a vendor of an EHR which does not offer a practice management module may nonetheless build “data bridges” to commonly used practice management software products, allowing practices to mix and match products that may better suit the practice's needs, budget, and profile. Not uncommonly, one EHR product may not fit all the needs of a practice, and a separate photo management product (see below), patient education system (see below), or digital simulator program may be desired. Ideally, these should also be integrated as much as possible, even when provided by competing vendors. Integration reduces the requirement for double or triple entry of patient demographics in each program and can obviate the need to open multiple screens and programs with different sign-ons and user interfaces. One positive result of the more widespread adoption of EHR programs among physicians and hospitals is the potential (although as yet unrealized) promise of long-needed progress in interoperability among multiple vendors of medical record and other health information technologies. Market demand is likely to drive further innovation in this area.

Upfront investment of time – know your EHR

Overall, it is advisable that the plastic surgeon, office manager, and key staff members take the time to understand the capabilities of the EHR and consider how it can best be used to

limit manual entry and increase efficiency and flow with automatic templates, linked fields, and automated alerts and tasks. Taking the time to familiarize oneself with the features of the program and configuring the system to allow the office to take full advantage of the software will encourage further efficiencies and decrease frustration in the long term. Physicians should expect to take time off (both physician and staff) for appropriate training and implementation, and should expect decreased productivity for many months, possibly years. Interestingly, though, some studies have shown that despite the frequent reduction in clinical volume that many practices encounter even years after EHR implementation, revenues have increased, presumably due to better capture of revenue with more accurate billing and coding, and more efficient workflows on the practice management side.

Photo system

Most plastic surgeons will find the photo systems offered by their EHRs to be inadequate, as they cater to primary care and other physician specialties. Accordingly, plastic surgeons may find it better to purchase or subscribe to a dedicated photo management program that links with the EHR.^{11,42} Ideally, the system should allow direct uploading from the tablet device, camera or smartphone without needing to first download to a hard drive or needing to upload and assign to correct patients at the end of the day. Categorizing photos with metatags for demographics, surgeon, facility, diagnosis, procedure(s), and other considerations like implant size and position can provide important context for building dynamic galleries without having to duplicate photos. The process for assigning tags to the image should not be laborious and tags should be easily searchable. Certain tags such as photo date and patient demographics should be automated, especially if linked to the EHR. In such a system, it would be feasible, for example, to search for all 6-month postoperative pictures of a female breast reduction patient between the age of 28 and 40 years old who had at least 600 g of reduction. Some photo systems also allow the physician to immediately annotate the image and save the annotated image as a separate (“flat-tened”) file. This is an effective patient education and risk management tool as well. When a patient can see her asymmetries or other issues visually marked or the proposed procedure illustrated (especially when done in real time by the surgeon on a tablet and broadcast to a large screen in the examination room, creating an immersive educational experience), it may increase her understanding of the limitations while simultaneously increasing her comfort with the procedure. The manner in which the photos are presented to the patient is also important. Ideally, the program should permit before and after images to be shown side-by-side and saved as such and printed with a specified number of images per page. Access to the patient's images should be enabled via a laptop or desktop computer, tablet device, or smartphone. Some programs¹¹ allow the physician to give patients access to some or all of their images via a patient portal, and others allow patients to upload their own images to their account as well. This shared access may encourage happy patients to share their experiences with prospective patients.

When transferring the photos for use on a website or PowerPoint presentation, authorized individuals with access to the photos must be vigilant that proper consent has been

obtained from the patient for online use, and that identifying information has been removed. This includes the metadata tags assigned to the photo (such as patient name, gender, date of birth, procedure, date, etc.) which may remain associated with the photo and “readable” to a web search engine like Google. Consequently, if a plastic surgeon is unaware that this metadata must be removed from the photo, a well-meaning friend of a patient may Google her friend’s name only to be directed to a set of images in a plastic surgeon’s online breast augmentation gallery. If identifying features like tattoos are easily recognized, this can add to the risk of privacy violations. Similarly, some of this same information can sometimes be viewed inadvertently when the mouse is rolled over the image. These incidents may not only lead to loss of business from disgruntled patients but may lead to charges of HIPAA violations or other legal and financial liabilities.

As is true with the EHR, it is equally important with a vendor of photo management systems to delineate in the contract who owns the data/images, who bears the responsibilities for maintenance and what are the conditions for and obligations following termination of the contract (see discussion in Contracting considerations section, above).

Practice management

Integrated single-vendor software products may include components for practice management, scheduling, billing, clinical documentation, and follow-up marketing. An increasing emphasis on interoperability of healthcare information systems provides practices with more choices and the ability to bring together digital tools from a variety of vendors. While there is often much discussion by physicians about the documentation and note-generating aspects of an EHR, perhaps more important to the overall health of the office is the practice management system used. Traditionally, practice management systems focused mainly on the billing and coding process and tracking accounts receivable. However, sophisticated modern practice management systems can streamline workflows and reporting and increase revenue capture while potentially reducing costs.

Billing

Even in the traditional arena of billing, some newer practice management programs will automatically check patient eligibility information, including verifying that the patient’s insurance is still active, identifying the amount of the deductible and how much has been met, listing benefits for in- and out-of-network visits and for inpatient and outpatient procedures, cataloging copays for studies and labs, and furnishing formularies and benefits explanations for prescription medications. This information may facilitate the collection of appropriate copays and deductibles at the time of the visit or more accurate decision-making regarding procedures and orders. Some systems have an E/M (Evaluation and Management) calculator which helps the clinician code the appropriate billing level for the office visit based on the information gathered in the progress note. For example, a sophisticated EHR using a structured data model can use Medicare E/M coding guidelines to determine the number of history, physical examination and review of systems bullets that have been satisfactorily documented, as well as provide the physician a way to override the automated

coding and bill based on time and complexity of the encounter. Many EHRs provide tools to assist in selection of the appropriate CPT and ICD codes, and may even automate the process based on anatomic and clinical data entered in the course of the progress note’s creation. After the claim is generated, most systems have a process called claims “scrubbing”, in which the claims are checked for errors prior to submission. When available, the claim can be sent either directly to a third-party payor or more commonly to a billing clearinghouse, which then sends the claims to the appropriate third party. Ideally, the interfacing of the practice management program with the clearinghouse will automatically send secondary claims to the supplemental insurance payors, where applicable, and even generate paper statements to patients as needed for billing the patient’s out-of-pocket component. Automation of this process reduces the dependency of a practice’s revenue on the caliber and dedication of personnel in the office, and when set up appropriately, reduces the frequency of missed or denied claims.

Reports

Popular practice management systems also allow access to customizable reports that help the practice track outstanding unpaid claims, revenues per facility, revenues per claim, revenues per employee, volume by procedure, etc. Historically, many such reports were difficult to obtain and were rarely generated in real time. With more sophisticated systems, practice managers and physicians can assess the viability and efficiency of their practice on demand.

Theft prevention

Practice management programs may also help decrease the risk of theft, embezzlement and similar issues by allowing books to be “hard-closed” at the end of each day. When the hard close is performed, monetary amounts and transactions can no longer be added, removed, or altered. Additionally, robust inventory management systems help track how many products have been sold, by whom, and how many products should remain in inventory, helping to mitigate against “lost” inventory, to prompt timely restocking, and to facilitate more accurate tracking of revenue generation from the sale of each unique product stock-keeping unit (SKU).

Customer relation management

Newer systems also feature customer relation management (CRM) modules for tracking leads, following patients for recurrent revenue opportunity, and engaging patients with appropriate marketing materials. Some of the common features of CRM products include the ability to send targeted timely emails or letters based on patient demographics, procedure types, time elapsed from prior appointment dates, etc. Properly used, CRM can be deployed even before the patient comes into the practice. The system can start engaging the patient the moment an inquiry is made on a website, a subscription to the practice’s electronic newsletter is enrolled, or a patient appointment call is made. When these inbound communications are received from prospective patients, automated customized emails or letters can be sent prepopulated with appropriate information and on a predetermined schedule. For example, in the case of a new breast

enhancement patient, the process may be set up as follows: an initial welcome message is sent after the patient has scheduled an appointment, an appointment reminder is delivered via SMS or email one week after inquiry and again 3 days before the scheduled appointment (with a request for the patient to acknowledge receipt and confirm the appointment time with a quick text or reply which is automatically registered in the system), a “thank you for coming” message with a succinct visit summary is delivered the day after the patient is seen, a follow-up message is issued asking if the patient desires more information if an appointment for surgery has not been scheduled within 4 weeks, and so on until after the surgery is completed. Reminders for postoperative appointments, due dates for neurotoxin and filler treatments, special promotions and events can all be delivered and tracked with sophisticated CRM tools.

On-site patient education

Using digital technology for patient education can enhance patient comprehension of complex medical information, and modern devices and software products can make this a highly interactive experience. When used effectively, such technology can increase the patient’s confidence not only in the treatments selected, but also in the surgeon whose competence may be reflected in the selection of state-of-the-art modern tools used in the office.

Digital educational materials

The office encounter may be enhanced by interactive informational videos or materials that patients can be viewing in the reception area or in the examination room as they are waiting to see the physician (Fig. 36.3). These may include slide presentations, animations, video tutorials and other media, and may be professionally developed, licensed from third parties, or generated in-house by the physician’s practice. Digital information on other available procedures and products may open the door to further discussion on a topic or procedure about which the patient was previously unaware. As stated previously, during the encounter the real-time use of photographs and illustrations that can be annotated may help the surgeon explain the procedure in detail or show asymmetries and other considerations that are specific to the patient.¹¹ More elaborate programs allow the annotated images to also be saved seamlessly to the patient’s chart. Some tablet EHR products also boast highly detailed virtual anatomic atlases featuring multiple touch-sensitive zones, allowing explanation of pertinent anatomy and techniques with multiple views and layers (Fig. 36.4). The initial consultation is often a prime opportunity for plastic surgeons to showcase their artistic skills with quick sketches of procedural steps, incision locations, etc., drawn before the patient’s eyes in real time.

Digital simulation

Digital simulators may also allow the surgeon to better demonstrate to the patient and companions the possible outcomes of a procedure, and may also assist in surgical planning. Most of these are stand-alone systems that in some cases can be linked to the practice’s EHR. Some require special hardware and a dedicated area of the office designated as an image

capture room.⁴³ Other systems⁴⁴ only require an iPad, camera phone, or regular camera to capture three traditional-position images (frontal, right lateral and left lateral) in any room (Fig. 36.5). With sophisticated computer algorithms, the photos are interpolated into a three-dimensional image that can then be manipulated in the software. The same system also allows three-dimensional scanning with a commercially available sensor attachment for the iPad (Fig. 36.6). The resultant image can then be manipulated to help the patient visualize possible outcomes and provide useful feedback about specific aesthetic goals (Fig. 36.7). For breast augmentation planning, virtual breast implants selected from a menu categorized by manufacturer, size, shape, and dimensions may be added and different implant choices may be viewed side-by-side. With multiple views and what-if scenarios, the patient can assess differences in projection, shape and width. For example, three-dimensional modeling can help the patient better understand the difference between a shaped or round implant and help her to decide whether the projected result is worth the added expense. For a patient seeking breast reduction, digital simulation may help to show the patient a representative image of what a reduction of 500 g of breast volume (as may be required by her particular insurance) would look like, to help her decide if she would like to commit to insurance coverage, or instead pay out-of-pocket for a more limited breast reduction that preserves more volume. The program allows for differential subtraction of volume on each side which can be helpful in planning secondary breast revision cases and post-mastectomy reconstruction. In the evaluation of the mastectomy patient for post-mastectomy reconstruction, this feature may permit the surgeon to subtract the entire volume of the breast and then place a variety of virtual implants to assess the best direct-to-implant choices for the patient. When counseling candidates for augmentation mastopexy, who often have difficulty understanding the necessity of both components in their surgical plan, the simulation helps to illustrate what the breast may look like with an implant alone without the mastopexy and vice versa. With facial and body images, the programs allow the surgeon to simulate various procedures including reshaping, retexturing, and filling with a variety of topical treatments, injectable products, laser and energy devices, liposuction systems, etc. The surgeon can also model widening/narrowing, advancing/recessing, and raising/lowering of various structures such as the chin, brows, nose, eyes, cheeks, etc. One vendor’s software fabricates full facial replicas with 3D-printing technology, and integrates with some 3D camera systems used for other clinical simulation tasks to create an even more comprehensive visual and tactile representation of the patient’s features for more detailed modeling.⁴⁵

Some programs allow the patient to upload pictures securely from home to the physician’s website (Fig. 36.8). The photos are incorporated into simulation software, and patients are then encouraged to schedule an office visit to see these simulations and discuss treatment options with the surgeon. In so doing, these tools move beyond education and may serve as a means of differentiating the surgeon in the market and recruiting prospective patients. Finally, some programs allow patients secure online access to a portion or all of their images remotely, as determined by the physician, and some offer easy social media sharing options. Thus, happy patients may share their results with friends (Fig. 36.9).

⬅️ Brow Lift

Brow Lift Risks

Brow Lift Risks:

Each year thousands of women and men undergo successful brow lift procedures, experience no major problems and are happy with the results. Significant complications from a brow lift are infrequent. However, make sure you understand what surgery involves, including possible risks, complications and follow-up care.

A brow lift poses various risks, including:

- Excess scarring.
- Facial asymmetry.
- Temporary or permanent hair loss near the incision.
- An accumulation of blood under the skin (hematoma).
- Changes in skin sensation in your brow and/or forehead area for a few months up to two years.
- Forehead nerve damage which can result in loss of the ability to feel or raise eyebrow and/or forehead area.

- The need for revision surgery to correct rare complications of the brow lift surgery.

Like any major surgery, a brow lift poses a risk of bleeding, infection and an adverse reaction to anesthesia. It's also possible to have an allergic reaction to the surgical tape or other materials used during or after the procedure.

You can help minimize certain risks by following the advice and instructions of your surgeon, both before and after your brow lift surgery. If you have any concerns about the risks involved with a brow lift surgery, please consult your surgeon.

⬅️ Rhinoplasty

Rhinoplasty Overview

About Rhinoplasty:

Rhinoplasty, also known as nose surgery, is a common procedure to improve the appearance and proportion of the nose. It can also be performed to correct birth defects, breathing difficulties, or to repair deformities caused by injury. Changing the size, shape, or proportions of the nose can often help improve self-confidence.

Rhinoplasty Considerations

Rhinoplasty Considerations:

The best candidates for rhinoplasty have realistic expectations and are interested in improving the appearance and/or function of the nose. Before you decide to have rhinoplasty carefully think about your expectations and discuss them with your surgeon. The following conditions could indicate that rhinoplasty surgery is right for you:

- Nose is not in proportion to the rest of the face.
- Nasal tip is drooping, upturned, hooked, or enlarged.
- Nose bridge has humps or depressions.
- Nostrils are too large or wide.
- A history of nasal obstructions or breathing problems.

Rhinoplasty is often postponed on younger patients until the nose has completed its growth, typically around 15 or 16 years of age.

Open vs. Closed Rhinoplasty

The closed rhinoplasty approach uses surgical incisions inside the nostrils, avoiding a visible scar. This approach may reduce swelling time. However, this approach limits access to the internal structure of the nose, so more complex rhinoplasty procedures may require the open approach.

The approach you choose greatly affects the results. Your surgeon will help you choose the approach they feel is most appropriate for your goals and the results you desire.

Open vs. Closed Rhinoplasty:

There are two different techniques, or surgical approaches, used for rhinoplasty. These include open and closed rhinoplasty. Patients considering nose surgery should be aware of the differences.

The open rhinoplasty approach, also called external rhinoplasty, uses a few hidden incisions made inside the nostrils and adds a small bridging incision, called a trans-columellar incision, to connect the right and left nostril incisions. With the addition of this tiny visible incision, the nasal skin can be folded upward (much like opening the hood of a car) giving the surgeon more access to the internal structures of the nose. This allows for more precision and ease while sculpting the nose. When properly performed, the open rhinoplasty incision heals remarkably well and becomes nearly invisible.

Fig. 36.4 Illustrations that can be annotated and saved for the patient to access later via their portal can be an effective patient education tool. (© 2015 TouchMD, an ALPHAEON Company. Used with permission. All Rights Reserved.)

However, consideration should be given to whether the simulated image can be misconstrued as an implication of a guaranteed result – all images and all sessions should emphasize that the images are not a guarantee and are estimates only to be used for educational purposes. Printing a disclaimer to this effect on any image that the patient is able to view outside the office or which goes into the medical record may serve an important role in setting expectations and documenting the limitations of digital simulation tools.

On-site clinical information and decision-making

Digital technology may also assist the surgeon in clinical information and decision-making. As mentioned in the previous section, digital simulation is not only a patient education tool but can be used to help patients and surgeons plan and choose appropriate techniques, breast implants or other procedural components at the time of the office encounter.

Fig. 36.6 Image processing systems may also allow for images to be captured with the Structure sensor scanner on an iPad, creating instantaneous reconstruction. (Image courtesy of Crisalix.)

Digital technology may also allow access to a specific specialist consultation from a remote location. This may be in the form of an intra-specialty or inter-specialty consultation. With newer products that are HIPAA-compliant and with the use of high definition video camera systems, the remote consultant can see and hear the interaction and advise in real time during the patient encounter. This may bring needed expertise to aid in the care of patients in a remote or underserved region with limited services or may facilitate additional expert opinion for complex cases. Military battlefield triage and surgical stabilization may be aided by similar telesurgery technologies.

Digital tools have also granted easier access to services during a visit that were previously unavailable. For example, translation services are available via a smartphone app⁴⁴ where the patient's language is selected, a translator calls the phone and provides translation for the entire interaction from a remote location. This is also available for patients requiring sign language interpretation via an online platform,

Fig. 36.5 Some systems allow images to be captured either with a traditional camera or mobile device in three views and uploaded for automatic 3D reconstruction. (Image courtesy of Crisalix.)

Fig. 36.7 A 3D reconstruction of the breasts can be manipulated to choose different implant brands, size, shape, texture, pocket position. Options for mastopexy and implant/volume subtraction also exist. Sample before and after view. (Image courtesy of Crisalix.)

increasing accessibility and decreasing the cost to the office of hiring an in-person sign-language interpreter for compliance with the American Disabilities Act (ADA).^{46,47}

Perioperative digital technology

Digital technology is increasingly playing a role in the preoperative, intraoperative and postoperative phases of patient care. Following initial consultation and establishment of a patient's candidacy for surgery, a number of digital tools, including devices and software systems, are available to properly plan, execute, and immediately monitor patients after complex procedures. As capabilities advance and processor

speed, chip memory, cloud storage infrastructure, and mobile/wireless technologies evolve, a fully integrated operative suite with a system of interconnected devices and programs is not only feasible, but may become the norm in the near term.

Preoperative work-up

Assessing photographs in preoperative planning

The preoperative workup for a patient often begins during, or shortly after, the initial consultation. Properly captured patient history and physical information in an electronic medical record can be reviewed along with digital photographs that are marked to the patient's chart. As described in

Fig. 36.8 Some programs allow the patient to upload pictures securely from home. The patient is then encouraged to schedule an office visit in order to see the simulations and discuss treatment options. (Image courtesy of Crisalix.)

Fig. 36.9 Some systems offer patients remote online access to designated reconstruction images with social media sharing options. (Images courtesy of Crisalix.)

the Photo system section above, sophisticated EHR tools and photography archiving systems allow for categorizations of patient photos with metadata tagging for properties like procedure type, date of procedure, diagnosis, body location, patient age, gender, insurance type, place of service, operative phase (pre-, intra-, or postoperative), etc. A dynamic registry that contextualizes the patient's photographs can allow the surgeon to view a patient's preoperative photos among those of other patients with similar demographic, anatomic or other characteristics, to build a tailored operative plan. For example, the surgeon planning a rhinoplasty on a 30-year-old African-American patient may label her photographs with tags like "dorsal hump reduction", "African-American", "30-35", "open tip", etc. The surgeon could compare this index patient's photos to those of other patients whose photos were similarly tagged. The surgeon's pictorial record database becomes richer and more easily mined for the kinds of photos needed in any given context by being able to filter and sort through images based on these kinds of tags. Some standalone applications⁴⁸ provide such searchable metatagging and cataloguing of photo galleries on tablet devices (Fig. 36.10).

Digital simulation in preoperative and intraoperative planning

Additionally, photography archiving software programs equipped with morphing and annotation tools allow the

surgeon to non-destructively mark up a set of preoperative photographic images to incorporate preoperative planning ideas. This is commonly performed in rhinoplasty and breast surgery, where unmarked and marked reference photographs obtained prior to the onset of swelling and other intraoperative changes can serve as a continuous guideline throughout the conduct of an operation. It is particularly useful to have the ability to tag photographs with appropriate metadata asynchronously to the patient visit, so that additional pertinent information can be annotated to an image set even after the patient has left the office. Accessing photographic records remotely via cloud-based systems or virtual private networks (VPNs) allows the surgeon to be reminded of the surgical plan, to add information that may be generated after contacts with the patient, and to print or view photos when delivering care at a remote point of service (for example, when performing surgery at a hospital using a different, on-site record system).

Preoperative quotes and informed consent

Estimating financial responsibility for patients for aesthetic and reconstructive procedures is an equally integral part of plastic surgery office workflow, and the process of obtaining informed consent is, of course, critical to proper patient care, serving as a safeguard for proper procedure selection and as a legal record of the information provided to the patient.

Fig. 36.10 MyAppwRx.com images. (© 2015 AppwRx, used with permission. All rights reserved.)

Many EHR systems incorporate consent and quoting modules that automatically populate from information documented into the EHR from the clinical encounter, in some cases generating ICD-9 and ICD-10 codes, CPTs and fee schedules automatically. One of the earliest programs with this functionality was a client-server software program that created custom surgical quotes and informed consent booklets prepared for a specific patient based on procedures proposed and selected by the surgeon or appropriate office staff for populating the document outputs.⁴⁹ Many new software tools allow the patient to be sent quotes and consent forms via privacy-protected portals (often the same portals created for the patients to access pre-consultation educational materials and intake forms), so they may be reviewed by the patient, shared by the patient with family or caretakers, and, in some cases, completed. HIPAA-compliant online systems like DocuSign may be used to capture electronic signatures if deemed appropriate by the surgeon. The American Society of Plastic Surgeons (ASPS) informed consent library is available in CD and digital download format for surgeons to print and use in the office; some EHR systems allow pre-existing forms to be converted into smart PDF or other formats that allow signatures to be captured in the EHR application as well. Alternatively, other EHRs facilitate copy-and-paste functionality that allows the content of other consent forms to be “digitized” into the EHR’s library of forms.

Preoperative labs and studies

In addition to surgical quotes and consent tools, preoperative planning includes the ordering and reviewing of laboratory, radiographic, or other clinical data, as well as provision of prescriptions for perioperative medications. Most EHR systems in the United States are equipped with capabilities for electronic prescribing through Surescripts or similar platforms which connect to most pharmacies, reducing the requirement for generation, signing, scanning and faxing of paper prescriptions. Similarly, electronic computer provider order entry for laboratory and radiographic studies is built into many EHR programs. In many cases, these provide a means for the direct electronic transmission of orders to laboratory centers like Quest and LabCorp as well as for the receipt and filing of the results into the patient’s record. This automation holds some promise for accelerating the process of ordering and reviewing labs for the surgeon and office staff, and, where available, can be applied both preoperatively and postoperatively. Radiographic images viewable in PACS systems can sometimes be directly incorporated into the medical record along with the radiologist’s reports.

Automated preoperative workflows

The wide array of integrations between healthcare information technologies, often employing the Health Level 7 (HL7) language of data transmission, holds promise for additional methods of automating workflows.⁵⁰ Already, many practice management (PM) systems are integrated with the EHR programs of other vendors, allowing a “mix-and-match” approach to selecting office software solutions. Some vendors offer all-in-one solutions with EHR, PM, inventory and other features with internal integrations allowing automatic transfer of data such as diagnosis, date of service, procedure codes,

surgeon and patient information, etc., between the component modules. In some cases, this allows customized “workflow ladders” of task assignment and accountability chains to be configured in the software, where specific tasks involved in a preoperative or postoperative protocol for a patient can be assigned to individual staff members and the “baton” handed between them as steps in the protocol are completed. Well-integrated systems also allow these steps to be documented into the EHR, memorializing the date, time, responsible staff member and any notes pertinent to the workflow. As mobile technologies mature further, secure messaging and task recording on mobile devices help facilitate truly paperless office workflows.

Preoperative risk assessments and tools

In some cases, automation can also be applied to algorithms for preoperative risk assessment and management. For example, data entry tools in EHR programs can permit calculation of a Caprini DVT risk score, along with peer-reviewed evidence-based recommendations for appropriate prophylaxis. Calculation of ASA score, Fitzpatrick Scale, and other metrics is feasible with protocols coded into software for the perioperative patient evaluation. Some EHR vendors provide customization tools that allow practices to digitize their existing forms for such purposes, often working in tandem with the surgeon and staff in a collaborative development process. Such systems can help surgeons and facilities maintain compliance with documents required by AAAASF (American Association for Accreditation of Ambulatory Surgery Facilities) and other accreditation bodies, by permitting digitization of the necessary surgical checklists and other forms.

Preoperative modeling

Patients requiring more elaborate preoperative workups for craniofacial, microsurgical or other complex procedures can also benefit from digital technologies. While its necessity is not clear in all cases, digital angiography is commonly utilized as part of the preoperative assessment of patients undergoing perforator flap reconstruction and other microsurgical procedures. With the advent and increasing popularity of 3D printing, custom mouldages and cranial prosthesis for complex, composite craniofacial reconstructions for trauma, oncology, or craniosynostosis can be architected, utilizing 3D reconstructions of CT, MRI and other radiographic data along with digital photography to model the multi-dimensional topography of the patient’s current or anticipated defect. Sophisticated CAD/CAM tools^{51–53} can be used to create the anatomic models from which implantable constructs of titanium, methylmethacrylate (MMA), acrylics, hydroxyapatite (HA), bioceramics, polyetheretherketone (PEEK), and other materials can be machine-fabricated. Whole structure implants such as custom mandibular titanium plates may also be designed and manufactured. Composites of biologic and inert substances incorporating dermal matrices, stem cells, bone graft, chondrocyte scaffolds and other materials can also be designed and modeled. The availability of custom tissue engineering products from companies like Organovo and relatively inexpensive consumer-focused 3D-printing devices like the MakerBot holds promise for considerable ongoing innovation in preoperative design and prototyping for complex procedures.

Day of operation

Immediate preoperative digital technology

Once the patient has arrived for surgery, a number of tools are available for the immediate preoperative assessment. Many bedside digital vital sign monitors now include Bluetooth connectivity as well as integration directly into EHRs. Additionally, remote home vital sign monitoring is available from a variety of application vendors, with biometric parameters tracked by tools like HealthKit from Apple or Google Fit. Certain EHRs can pull forward medical history contained in prior clinical notes for the surgeon, anesthesiologist or other providers to review in the preoperative holding area. Immediate preoperative patient education can be enhanced similar to the initial office consultation, with streaming video content available through Apple TV, Google TV, and other wireless devices broadcast to video screens in private holding rooms. Preoperative checklists for the operating room staff can be put into clinical workflows in the EHR with electronic signing and attestation available for the appropriate staff members.

Intraoperative monitoring

The operating room is another venue for integration of digital technology in the care of the plastic surgery patient. Digital anesthesia monitoring is available in many operating rooms, although direct integration of the data into EHRs remains a challenge for many vendors. Often, this continuously acquired, streaming data is condensed into photographic summaries which serve the purposes of documentation but may be limiting in terms of data analysis capabilities. More direct integration of data from these systems into EHRs is anticipated and promoted by the FDA, Center for Medical Integration and other organizations, consistent with the HITECH Act's goal of promoting interoperability.⁵⁴ Other digital innovations may further improve patient safety; for example, radio-frequency identification (RFID) technology is being used to monitor lap sponges in the operating room. Companies are currently working on the concept of data fusion, which integrates various inputs such as imaging modalities and software algorithms that allow a hybrid 3D output, for example, or an integrated display of all relevant clinical information that could be real-time, streamed on mobile platforms, and potentially allowing for the superimposing of data and other image on a surgeon's visual field, either through a screen monitor or a wearable platform for real-time feedback/imaging during a procedure.⁵⁵

Intraoperative communication and collaboration

The surgeon in the operating room can also take advantage of certain digital technologies where appropriate. Digital point-of-view (POV) camera devices like the GoPro camera⁵⁶ and Google Glass can facilitate education of students and residents in the OR or at remote sites, providing the surgeon's vantage point to interested observers, allowing recording of surgical procedures for educational, marketing or quality assurance purposes, and providing a clearer picture of hard-to-see small spaces, like the nasal vault during rhinoplasty. Some surgeons utilize such technologies to engage in additional hands-free communication as necessary with staff and other parties outside the operating room. Telesurgery in

combat field hospitals, developing countries, rural locations, and other points of service may be facilitated through these POV technologies, which permit a remote surgeon to provide guidance and instruction to treating providers on site, possibly providing improved patient stabilization, triage, and second opinion consultation. Already there have been numerous publicly reported examples of surgeons utilizing Google Glass in surgery, including augmented reality overlays of surgical illustrations and procedural steps that are superimposable upon the patient's anatomy to help guide the conduct of a procedure.^{57–59}

Intraoperative tools for surgical decision-making

Surgeons working closely with pathologists on intraoperative pathology reporting may have access to sophisticated integrated digital pathology solutions incorporating smart digital scanning, image processing, archiving and analysis.⁶⁰ The surgeon engaged in microsurgery may utilize operating microscopes equipped with digital optics and video recording systems, and implant digitally monitored implantable Doppler probes to assess anastomotic patency. Tissue perfusion quality may be ascertained with the use of technology allowing intraoperative decision-making for debridement of tissue at risk for necrosis or interrogation of threatened vascular pedicles.⁶¹

Postoperative digital technologies

As a surgical procedure nears completion, continuation of perioperative workflow checklists can resume in the EHR. Geolocation systems employing protocols like global positioning system (GPS), radio-frequency identification (RFID), near-field communication (NFC), Bluetooth, wi-fi, internet protocol (IP), and uplink-time difference of arrival (U-TDA) cellular technology, can potentially track the whereabouts of the patient and staff members for accurate recording of surgical times, allocation of beds and human resources, and other location-based services. The intraoperatively placed Doppler probes can provide ongoing postoperative flap monitoring, and vital sign applications can stream continuous physiologic data to the physician's smartphone. Numerous additional uses of digital technologies can be envisioned and designed by innovative plastic surgeons in collaboration with engineers, software developers, and other clinical providers.

Digital technology between patient visits (including long-term follow-up)

Introduction

With advanced practice management/customer relationship management programs, monitoring with wearable technology and accessories, and online and other digital forms of patient and community engagement, physicians will be able to track and customize their engagement with their patients and community throughout their lifetime.

Direct patient communication

Communication in the form of HIPAA-compliant apps⁶² is already possible and widely available. The technology allows

for real-time, video, chat, and picture-sharing capabilities, as with the virtual consultations discussed previously.

Surgeons wishing to discard pagers and arcane answering systems may still provide round-the-clock phone contact accessibility to patients, hospitals and emergency rooms using free services such as Google Voice. The service can be set up such that, when the patient calls the plastic surgeon's Google Voice number, it will ring any combination of land lines, mobile numbers, desktop computers, etc., simultaneously. The phone call can be screened, answered, or sent to a cloud-based voicemail. Voicemails can be transcribed and emailed and/or texted to the plastic surgeons. Alerts can be set to ring with different tones and set to different answering messages depending on the number calling. In addition, the plastic surgeon can use Google Voice to return the call to the patient without revealing their home phone or mobile number. The plastic surgeon may also choose any area code for their Google Voice number. To the patient, the Google Voice number is like any other number. Google Voice also allows free landline and mobile number calls to the entire US, Canada and Mexico. Of course, it may be necessary to have a back-up system such as a very basic answering service plan, to mitigate in the event of natural disaster, or other possible disruptions to the surgeon's access.

Other postoperative patient engagement tools are designed specifically to track adherence to postoperative care protocols and field inquiries from patients during their recovery. In addition to the telemedicine applications described above, plastic surgery offices can take advantage of mobile applications with secure messaging, patient compliance questionnaires, and private photo sharing. The patient or caretaker can send photos of healing incisions or body locations of concern for a quick triage regarding the urgency of follow-up.

Enhanced postoperative recovery protocols that include step-by-step guidance for recovery (e.g., "Walk 10 steps every 3 hours on postoperative day one; advance from a clear liquid diet to a low salt diet on postoperative day 2, etc.") can be built into checklists or messaging sequences with automated callbacks and alerts when patients are not responding affirmatively to requirements.⁶²⁻⁶⁶

Patient monitoring with wearables and accessories

Follow-up after the immediate postoperative period may sometimes be achieved with virtual visits and wearable or portable technology for monitoring. Current technology already enables EKG tracings, noninvasive blood sugar monitoring, heart rate, and dermoscope readings at the hands of the patient. Portable ultrasounds and heart rate monitors, and pulse oximeters are also available as attachments to smartphones.

There is great potential for innovation in the field of patient wearables for monitoring. For example, in the area of wound care, one project is developing wearables that include multiple sensors to detect pressure, monitor for infection, and adjust negative pressure applied to chronic wounds.⁶⁷ Newer products⁶⁸ can provide real-time feedback on plantar foot pressure to aid in the prevention of ulcers in diabetics and patients with other forms of neuropathy. One company⁶⁹ offers a wearable device that provides gait, balance and other postural analysis to assist in physical rehabilitation. Numerous consumer health

wearables have gained popularity in recent years, including the Jawbone UP systems for portable heart monitoring, Fitbit activity trackers, and the Apple Watch. Third-party apps can integrate physiologic, nutritional and other activity data from multiple devices and wearables into single portals where patients can confer with caregivers and advisors to craft personalized wellness plans. Future advances might include sensors incorporated into implants, wound dressings, or directly into tissue. These could offer feedback and remote monitoring of the wearer of the implant, status of the wound, infection, malignancy, etc., with the capability to transmit the information for remote access via a mobile app or a physician portal. The use of long-term monitoring and patient engagement between encounters is still in its infancy in terms of technology and adoption, but the potential of a major paradigm shift in healthcare delivery appears promising.

Patient community engagement online

Postoperative patient care, much like patient lead generation, has been impacted by the popularization of social media, with patients regularly sharing results, testimonials and detailed descriptions of their patient care experiences through a variety of media vehicles, including Facebook, Twitter, Instagram, Snapchat, blogs, and other interactive forums. Newer "crowdsourcing" sites for discussion of practice paradigms and medical advice sharing have proliferated, affording a venue for dynamic discussions between patients and other patients or between patients and providers. Engaging in such forums requires the surgeon and office staff to be ever mindful of HIPAA and other privacy considerations, but nonetheless can provide important education for patients recovering from procedures. One of the more popular and heavily trafficked crowdsourcing sites for medical recommendations and advice in the aesthetic plastic surgery field⁷ entails many surgeons responding regularly to inquiries from prospective patients as well as those who have undergone procedures by other providers. Many surgeons actively curate their profiles and activities on that and other sites as part of a general social media and marketing strategy; a number of additional crowd-advice sites have steadily gained in popularity.^{14,70} Patient-centric forums⁷¹ that focus on specific disease experiences have also given patients as consumers of healthcare an important role in patient referral patterns, treatment evaluations, and clinical trial design. The digitally empowered patient can have an important influence on a surgeon's reputation, search engine optimization, and word-of-mouth marketing success via online review sites.³⁻⁷

Digital technology in plastic surgery education and training

Perhaps nowhere is there more promise for impactful utilization of digital technology than in the arena of medical education and training. A new era in training capabilities has dawned with the advent and popularization of highly sophisticated virtual and augmented reality simulators. The Oculus Rift^{72,73} and other⁷⁴ systems have both shown great promise for creating highly immersive, multi-sensorial experiences incorporating photorealistic 360° video environments, accompanying audio and, perhaps when combined with wearable sensors,

tactile feedback. The conceivable applications of such technologies for simulation of surgical procedures, resident skills assessments with feedback looping, microsurgical training replete with tremor reduction and highly detailed magnification, and other applications are myriad. Similar to the intraoperative applications of augmented reality cited above, other vendors⁷⁵⁻⁷⁷ are exploring methods to incorporate CT and other radiographic data into simulations, in combination with instrumentation that provides verisimilitude to the tactile experience of handling real tissues. While not a substitute for direct intraoperative experience, these tools could provide important adjuvant learning and preparation toolkits for students and residents, particularly in early years of training. Some institutions have begun using surgical simulation as a core component of residency training, with intraoperative feedback provided during the simulation and procedures recorded for subsequent debriefing. The intraoperative use of point-of-view (POV) technologies such as Google Glass and the GoPro camera can provide the ability to communicate from the operating room in real time with images, video and chat tools to enhance the education of residents and other surgeons. It may enhance the perspective of a resident who may or may not be physically present as another surgeon performs the procedure or, alternatively, it may augment the viewpoint of the attending surgeon who may or may not be in the same room, while the resident performs the procedure. With routine use, POV systems can help facilitate the curation of a large educational surgical video library that can be streamed remotely on demand.

These technologies, in addition to other simple HIPAA-compliant apps that allow real-time chat, video, and audio, can also enhance communication and education in the emergency department or during other consultations where a picture or video is much more effective than a verbal description. This can be extremely helpful in the appropriate triage and staging of patients with lacerations and complex wounds, some of whom can be appropriately managed in the emergency room (by emergency department staff or the plastic surgeon) while others require care in the operating room. They can also be used for assessment and education of practicing plastic surgeons who are learning either in a simulation or by evaluation of the surgeon's actual cases. Larger scale review of various surgeons' procedures could also lead to formulation of best practice guidance for operating efficiency that can enhance resident education and continuing medical education.

Even the classic anatomic atlas has experienced digital innovation: several products^{78,79} provide multilayered and multi-view anatomic images, allowing a walk-through of every layer of the human body and individual organs, holding some promise to potentially decrease the need for human cadaver-based dissection, or to provide educational resources to supplement cadaver dissections. Coursework in medical school and lecture series during residency can benefit from digitally deployed course syllabi using numerous e-learning and distribution programs, with surgical textbooks as well as articles from plastic surgery journals and assorted relevant periodicals available in electronic format for reading on iPad, Amazon Kindle, or other handheld e-readers and tablets. Continuing medical education is facilitated by online articles, quizzes, Inservice exams, and conference webinars, with participants being able to attend, rate and claim credits for certain such activities on any web browser-enabled device.

Plastic surgeons and residents interested in additional education and training in information sciences have numerous opportunities in both degree-granting and executive education certificate programs focusing on bioinformatics/medical informatics, information systems, technology-enhanced education, device and software innovation and entrepreneurship. Master's degrees in bioinformatics or information systems often may be obtained on a part-time basis, with limited time disruption on other professional obligations or clinical practice momentum. Many MBA programs, both part-time and at the Executive MBA level, offer coursework in technology innovation as well. There are also numerous industry symposia, both sponsored within the plastic surgery professional organizations and within the digital health space, focusing on technological innovation pertinent to patient engagement, medical records, photo-documentation, telemedicine and telesurgery, practice management software, concierge-level wellness coaching, device design, bench-to-market strategy, venture financing, etc. Several professional societies, including the Healthcare Information and Management Systems Society (HIMSS), the American Medical Informatics Association (AMIA), and others provide annual meetings and educational opportunities that afford physicians exposure to a wide array of vendor products and services, key opinion leaders, advocacy programs, regulatory guidelines and other offerings. Many of these symposia and meetings provide formal Continuing Medical Education credits and serve as professional networking venues. At the intersection of innovation, venture funding, and clinical applications are several organizations that provide online newsfeed content as well as sponsorship of such meetings; examples include Singularity University's Exponential Medicine conference, VentureBeat and its associated HealthBeat conference, Digital Health Summit, and many more.

Digital technology for the advancement of plastic surgery (research and clinical outcomes and advocacy)

The advent of inexpensive and highly scalable storage and processing capabilities, along with the ubiquity of handheld mobile technology and wireless communications, has opened up numerous opportunities to mine and analyze large datasets for trends and outcomes information.

Residents training in surgery, as well as board Diplomates who participate in Maintenance of Certification programs, may participate in data registries such as the Tracking Outcomes in Plastic Surgery (TOPS) and ABPS board collection modules. Other plastic surgeons are required to participate in the DataHub for accreditation of their ambulatory surgery facilities by AAAASF.⁸⁰ Clinically targeted registries such as the National Breast Implant Registry⁸¹ and the Patient Registry and Outcomes for Breast Implants and Anaplastic Large Cell Lymphoma (ALCL) Etiology and Epidemiology (PROFILE) registry⁸² (both cooperatively developed between the Plastic Surgery Foundation and the FDA), and the General Registry of Autologous Fat Transfer (GRAFT)⁸³ have also been developed out of the recognition that real data is needed to answer important questions of safety, efficacy, and long-term outcomes.

Some EHR platforms allow case information entered into the clinical record to be directly integrated into certain registry programs, reducing the need for double data entry and providing a natural method to track case volume and complications. Surgeons participating in state public health registries and alert systems may sometimes take advantage of direct EHR data exports through the Fast Healthcare Interoperability Resources (FHIR) or Direct Protocols for health information exchange that allow automatic uploading of data transfer with other programs, registries and systems. As EHR adoption increases, it is hoped that even more seamless interfaces with automatic information transfer and portable data models will ease the administrative burden on physicians and their office staff.

Gathering of large-scale volumes of data is facilitated by improvements in automated technology. When combined with structured data architecture and natural language processing, these aggregates, often called “Big Data”, hold significant promise for assisting the evolution of healthcare from evidence-based medicine to *precision* medicine, in which data informing the likely outcomes specific to a subset of a population or an individual can be utilized to facilitate better clinical decision-making and treatment protocols. Precision medicine can be informed by clinical information furnished through medical records, healthcare claims, crowdsourcing sites,

wearable technology, patient genomics, and other sources of individualized data.

Furthermore, as reimbursements from third-party payers becoming increasingly tied to value-based compensation, and as healthcare policy-makers increasingly regulate medical practice, the access to and analysis of Big Data will help plastic surgeons and their specialty societies substantiate anecdotal evidence of efficacy, safety, cost-effectiveness and other endpoints. Prospective data may also help mitigate against unsubstantiated panic with every potential question of safety, or alternatively, may identify safety issues before they trigger a national crisis.

Crowdsourcing of clinical workflows and outcomes data may allow the physician community to converge on best practices which maximize patients’ safety, longevity and satisfaction. Digital platforms that are easily accessed, easily shared among providers, and easily analyzed may also help plastic surgeons collaborate to conserve resources, streamline workflow, decrease redundancies across practices, and improve practice efficiencies. Some physicians are utilizing technology to create virtual group practices which maintain independent practice identity and autonomy while maximizing the efficiency, negotiating power, and influence of a collaborative group.
